Molecular Dynamics Studies of Polymer Systems

Jonathan Gay
4/26/2012

Abstract

The goal of this work was to determine if molecular dynamics as represented by the United-Atom method employed by the DL_POLY2 software package could explain polymer phenomena such as melting point temperature, glass transition temperature, crystallization, and density, and assess the effect of side group length, branching, chemical structure, length of polymer, and temperature. The verified model will then serve as a confident tool in the prediction of the properties of polymeric systems. The aim was to apply molecular dynamics simulations to polymers relevant to the running shoe industry.

Acknowledgements

I would like to thank Professor N. A. Deskins and Thomas Gabry for all their help. I know I asked for a lot over the past year. I appreciate all the support, guidance, and assistance they provided.

Introduction

Motivation: Running Shoes

Running shoes provide cushioning to the foot upon impact with the ground. The most common material used in the midsole of the shoe (the part of the shoe that provides the cushioning) is ethylene vinyl acetate or EVA foam. (Shorten, 2000, p. 4) This foam has air or other gasses trapped inside the cells of the foam that upon compression, exit the cell. (Shorten, 2000, p. 12) After the shoe has left the ground, and the EVA foam is not under compression, air is drawn back into the cells. This occurs because of the elastic properties of the EVA. This cycle repeats with every step taken. The rebound time of EVA foam ranges from minutes to hours. (Wilson, 2007, p. 1372) Eventually the cells start to become permanently deformed. (Wilson, 2007, p. 1371) The foam cells draw in less air at a slower rate, hindering the full expansion to their original position. Running shoes become 'worn out' when the foam cells no longer provide a satisfactory amount of cushion.

The degradation of polymers has yet to be fully understood due to their complex chemical nature. Degradation can occur from environmental interactions such as light radiation, heat, swelling, dissolution, scission, and chemical reactions with atmospheric oxygen for instance. (Callister, Jr., 2007, pp. 655-657) During the active lifetime of a running shoe the interest would be in modeling the deformation rather than the degradation of the polymer network. As waste is becoming an increasingly important topic, efforts to use to environmentally friendly polymers in running shoes have been on the rise. Modeling polymers to assess their properties is an important task towards understanding how running shoes perform and degrade with time.

Project Goals

The aim of the current work is to assess simple polymer systems that will lay the groundwork for eventually modeling complex EVA foam and its eventual deformation and degradation. Key areas for future studies include the modeling of various types of crosslinking and polymer orientations. The goal is to provide a foundation for running shoe companies to build upon. The ability to assess newly proposed polymers and their improved characteristics before experimentation will save time and reduce waste.

Background

Polymers

Polymers are large molecules of high molecular weight composed of repeating units called monomers. Most contain a high percentage of carbon and hydrogen. (Callister, Jr., 2007, p. 492)

Properties

The properties of polymers are affected by their different chemical and structural characteristics. Their composition (types of atoms, length of chains, degree of branching, etc.) determines these characteristics. For example, the degree of crystallization affects density, stiffness, strength, and ductility. The degree of crosslinking (described below) affects the stiffness, and the chemical makeup of the polymer affects the melting and glass transition temperatures. (Callister, Jr., 2007, p. 489)

Polymerization, or Growth of Polymers

Addition Polymerization

Addition polymerization usually occurs through radical addition, where an initiator molecule, usually peroxide, is degraded to produce two radicals. These radicals attack the double bonds of short molecules, in the case of polyethylene, an ethylene molecule, forcing an electron from the double bond to become an unpaired on the opposite side of where the peroxide attacked. This unpaired electron (radical) can now attack an ethylene molecule on its own, and continue the polymer growth. The unpaired electron on the carbon atom attacks the double bond of the neighboring ethylene molecule, creating a carbon-carbon single bond. This forces the other electron previously participating in the double bond to the other side of the molecule, opposite of the attack. This in turn creates another unpaired radical electron which continues to propagate the chain. (Wade Jr., 2009)

Condensation polymerization

Condensation polymerization forms polymers through the elimination of a small molecular weight byproduct when two reactant species come together. The reactant species can be the same or different molecules. The number of reactive sites each building block molecule has determines the type of polymer that can result from polymerization. Building block molecules with two reactive sites, termed bi-functional, form linear chains. A molecule with only one reactive site terminates the chain, whereas molecules with three or more reactive sites, tri-functional or higher functional monomers have the ability to form branching, crosslinks, and polymer networks. Typically condensation polymerization reactions are slower than those of addition polymerization. This type of polymerization also tends to produce lower molecular weight polymers. (Callister, Jr., 2007, p. 593)

Ring opening polymerization

Ring opening polymerization is a process that involves breaking open a cyclic ring to grow the polymer. This progression of chain growth can employ techniques from both types of polymerization described above (Davis, 2004, p. 44).

Basic Structures of Polymers Examined

Polyethylene

Polyethylene is the most basic of olefinic polymers, consisting of the repeating unit $-(C_2H_4)-$. This polyolefin is a homopolymer, consisting of only one type of repeating unit. (Callister, Jr., 2007, p. 496) Figure 1 below, shows the basic structure of polyethylene. Carbon atoms make up the backbone of the chain and are colored grey. Hydrogen atoms are colored white.

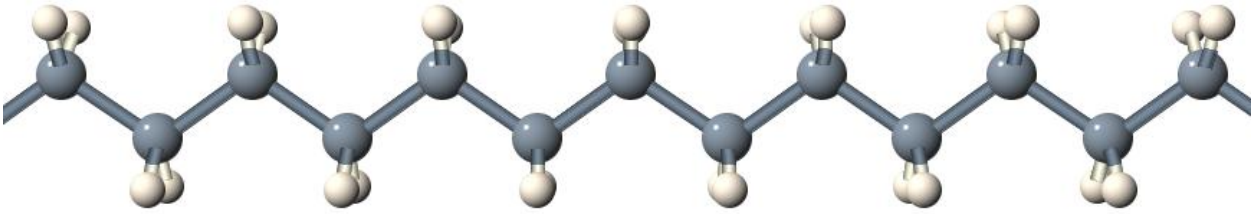

Figure 1: High Density Polyethylene (HDPE) Structure

Branched Polyethylene, or Low Density Polyethylene (LDPE)

Low density polyethylene is a branched version of polyethylene, where side chains extend out from the main chain. Figure 2 below is an image of LDPE where only the carbon atoms are shown.

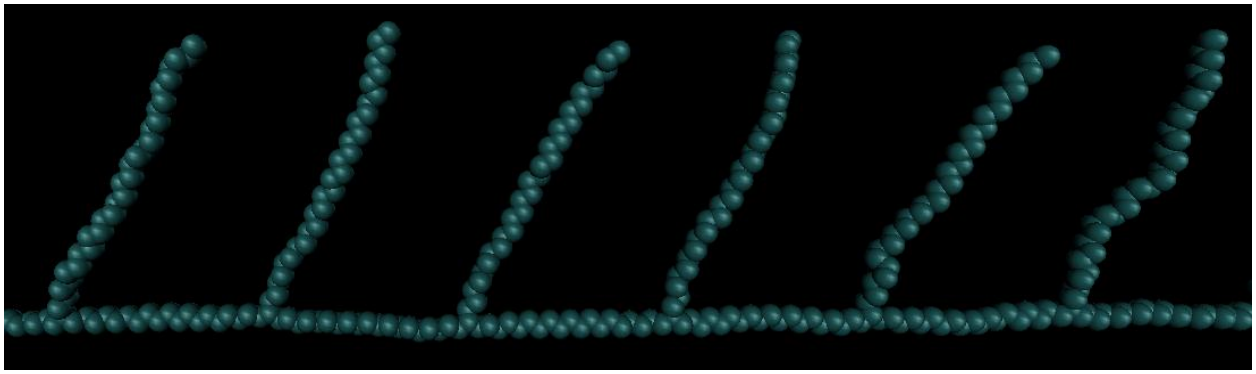

Figure 2: Low Density Polyethylene (LDPE) Structure

Polypropylene

Polypropylene is another olefinic polymer. From the basic polyethylene structure, one of the substituent hydrogen molecules is replaced with a methyl group. The repeating unit is $-(C_2H_3CH_3)-$. This polyolefin is a homopolymer as polyethylene is, consisting of only one type of repeating unit. (Callister, Jr., 2007, p. 496) Figure 3 below shows the basic structure of polypropylene. The carbon atoms are colored grey and the hydrogen atoms are colored white.

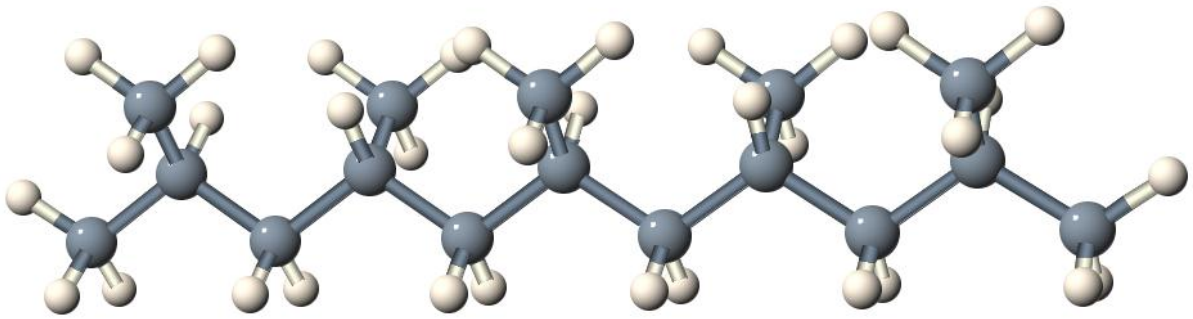

Figure 3: Polypropylene Structure

Ethylene Vinyl Acetate

Ethylene vinyl acetate is a copolymer. This term refers to a polymer chain with different repeating units (Callister, Jr., 2007, p. 495). The two repeating units are ethylene $–(C_2H_4)–$ and acetate $–(C_2O_2H_3)–$. Running shoes typically have 18 percent by weight vinyl acetate, with the remainder being ethylene. (Verdejo & Mills, 2002, p. 582) Figure 4 below shows the basic structure of ethylene vinyl acetate with one acetate group. The carbon atoms are colored grey, the hydrogen atoms are colored white, and the oxygen atoms are colored red.

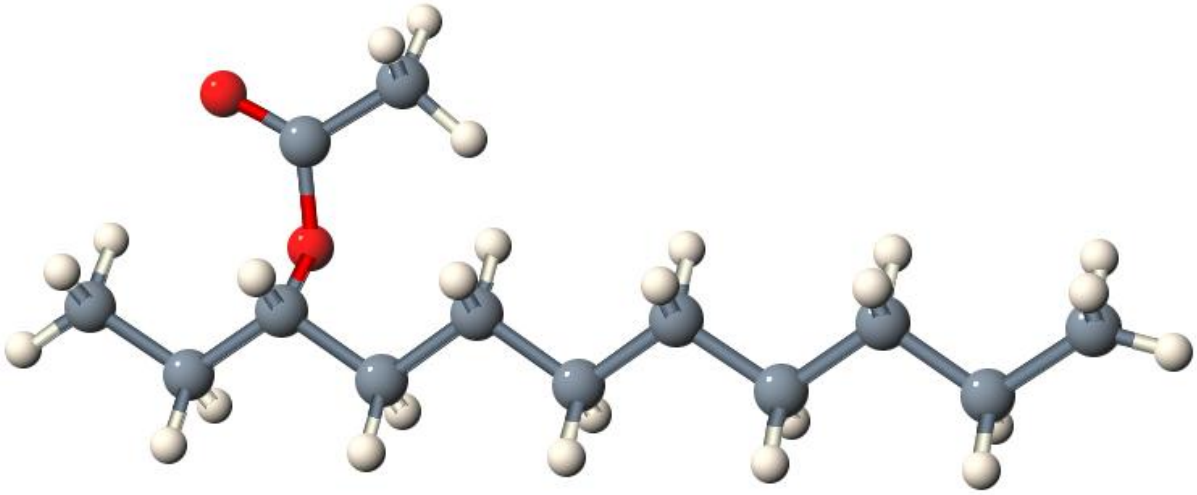

Figure 4: Ethylene Vinyl Acetate (EVA) Structure

Degree of Polymerization

The degree of polymerization, DP, describes the number of repeat units or monomers that have joined together to form a polymer chain. The degree of polymerization for a polymer is given by the equation $DP = M_n/m$, where M_n is the number average molecular weight of the given sample and m is the

molecular weight of the monomer. The number average molecular weight is a weighted average representing the molecular weight of the most abundant chains. For a given polymer sample, the degree of polymerization is the average number of monomers per polymer chain. (Callister, Jr., 2007, p. 498)

Critical Molecular weights

The critical molecular weight of a polymer is the minimum molecular weight that a polymer needs to have to exhibit its steady state bulk properties. At this molecular weight the chain dynamics cross over from free (or Rouse) to entangled (or reptation). Free chain dynamics explain the unattached nature of the polymers. They are free to move and slide over other chains without much hindrance. Entangled dynamics explain chains that are of a certain length where interactions with other neighboring chains greatly affect their movement. The chains are considered intertwined, as they are not able to freely move. (Drzewinski & van Leeuwen, 2006) Polymer chains with less than the critical molecular weight have transient properties. (Kausik, Mattea, Fatkullin, & Kimmich, 2006) Just as ethane, butane, and octane are essentially short chains of polyethylene and have different properties, polymer chains of different lengths have different properties as well. Only once the chains exceed the threshold length (or mass) known as the critical molecular weight, do they start to exhibit consistent properties. At this length the tangled nature of the chains allows the van der Waals forces to act steadily as the chains are hindered from moving freely over each other. Van der Waals forces are the long range attractive forces that act on neighboring molecules. Critical molecular weights are different for each polymer. Polymers exhibiting more flexible behaviors and minimal branching have much higher critical values than those with rigid backbones and high degrees of branching which promote tangling.

Branching

Branching is the term used for polymers that are not linear. Branched polymers are those that have multiple secondary chains that extend out from the main chain. (Callister, Jr., 2007, p. 502) Polymer branching occurs when monomers have more than two reactive sites, or are tri-functional or multifunctional. (Callister, Jr., 2007, p. 593) When the monomers have these unique properties, side reactions can occur at multiple points during polymer formation resulting in branching. The higher the degree of branching, the more the packing efficiency is reduced, effectively lowering the polymer density. (Callister, Jr., 2007, p. 502)

Crosslinking

Crosslinked polymers are created when adjacent chains are fused together by covalent bonds. The more places that neighboring chains are linked together, the higher the degree of crosslinking the polymer has. When polymers become highly crosslinked, they assume a three-dimensional structure and are termed network polymers. (Callister, Jr., 2007, p. 503)

Vulcanization was the first form of synthetic crosslinking. Natural and synthetic rubber when heated with sulfur form sulfur bridges or links between the long polymers. Vulcanization treats unsaturated polymers where the double bond in the backbone of the chain is broken and bonds to the sulfur crosslinking chain. (Encyclopedia Britanica, 2012, p. 1) These links are covalently bonded and effectively rebound the shape of the material after an induced stress, giving it elastic properties. (Encyclopedia Britannica, 2012, p. 1) (Odian, 2004, p. 740)

Unfortunately this basic method of vulcanization crosslinking does not work for saturated polymers like EVA or polyethylene. Organic peroxides are used to crosslink such macromolecules without double bonds. Peroxides when heated form radicals that are able to attack the backbone of saturated polymers and create sites for crosslinking. A common organic peroxide crosslinking agent for EVA is dicumyl peroxide shown in Figure 5 below. (Arkema, 2009, p. 5)

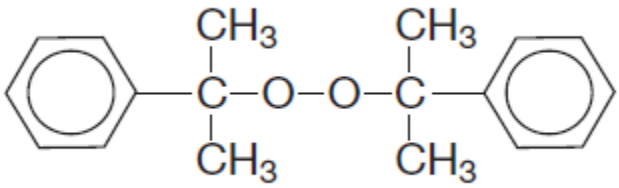

Figure 5: Crosslinking agent Dicumyl Peroxide Structure

Foams

Foams are expanded plastics that are more rigid than dense polymers at any given weight. Foams collapse under impact or compressive stresses, but are able to absorb much of the energy transferred to them, a basis reasoning for their use as cushioning agents in running shoes. Foams can be produced by injecting gasses into a quantity of polymers in the liquid state. Upon cooling, the plastic traps the gasses within the network forming a foam. (Encyclopedia Britannica, 2012)

Computational Chemistry and Molecular Dynamics

Simulations are important in the chemical industry as precursors to industrial change. Simulations of proposed processes are needed to assess changes in current processes or for the initialization of new ones. Computational chemistry and molecular dynamic simulations are used to examine the physical properties of molecular systems to determine the possibility of manufacture or implementation. Using these methods the individual atoms or molecules are simulated. (The NSF Blue Ribbon Panel on Simulation-Based Engineering Science, 2006)

Basic Theory

Computational chemistry, sometimes called theoretical chemistry or molecular modeling, combines quantum mechanics theory with the simplifying approximations of a model to solve practical problems. (Cramer, 2002, p. 2) The observable chemical properties of a system are fundamentally described by the theorems of quantum mechanics. (Cramer, 2002, p. 4)

The minimum input needed to model an isolated molecule is the types of component atoms and their relative positions. (Cramer, 2002, p. 5) Molecules are constantly in motion (bond stretching, bond rotation) and rarely at any given point have the same exact geometry as other molecules of the same type within the system. (Callister, Jr., 2007, p. 501) For the model to more closely represent actuality therefore, all molecular geometries are captured by molecular dynamics into what is known as a complete potential energy surface (PES). (Cramer, 2002, p. 6) Molecular dynamics simulations attempt

to ‘map’ the PES for given molecules to find local energy minima, or the most stable geometric configurations. (Cramer, 2002, p. 5)

Molecular dynamics simulation involves step-by-step solutions of Newton’s equations of motion. It uses atomic coordinates, or the relative positions of the atoms, comprised of inter-atomic distances, bend angles, and torsion angles, to calculate the potential energy of the molecule. (Allen, 2004, p. 2) The simulation runs through a range of each of these parameters to find the optimum geometry of the molecule, in which it has the lowest potential energy. This range of each of the parameters is defined by the force field potential used in the simulation. There are different force fields to choose from, each working best for different types of molecular systems. Some of them are described below.

Inaccurate properties of the bulk system result from simulations of small numbers of molecules, as a large part of them comprise the surfaces. To address this, periodic boundary conditions are introduced that surround the sample simulation box with replicas on all sides. The system becomes much larger and properties are able to be measured with the entirety of the system encapsulated with mirror images.

The current work utilizes molecular modeling as defined by Cramer (p4). The aim is “to focus on a target system having a particular chemical relevance (e.g., for economic reasons) and to be willing to sacrifice a certain amount of theoretical rigor in favor of getting the right answer in an efficient manner.” (Cramer, 2002, p. 4) Many simulations are based around simplifying approximations that decrease the time it takes for the computer to work through the calculations. For example, harmonic potentials are used to describe bonds and angles, but are commonly replaced by fixed values to save computational time. One simplification used in the current work, as well as in a many polymer modeling papers, is the United-Atom method. This method groups together multiple atoms into a pseudo atom. The number of parameters mentioned earlier, such as bond lengths and angles, therefore, decreases significantly as the number of ‘atoms’ in the system is reduced.

In molecular dynamics simulations, force field denotes the parameters of the potential used to calculate the forces acting on the atoms of the system being modeled. Different atom types are described with various defining parameters such as bonds, angles, dihedrals, and long-range interactions based on the particular surrounding environment of each atom. One such force field developed by William L. Jorgensen is known as OPLS (Optimized Potential for Liquid Simulations) force field, shown below in Equation 1. This force field describes the velocities of the atoms within the system through summations of the bonds, angles, torsions, and Lennard-Jones potentials. (Marcon, Vehoff, & Ghiringhelli, 2007) In Equation 1, b is the bond length, θ is the bond angle, b_0 and θ_0 are the equilibrium values, K_b and K_θ are the force constants, ω is the dihedral angle and V_n the corresponding force constant, and γ is the phase angle. The parameters r_{ij}, ε_{ij}, σ_{ij}, q_i, and q_j are the ‘atom’ separation, Lennard-Jones well depth, Lennard-Jones size, and partial charges, respectively, for the pair of interaction sites i and j. (Duan, et al., 2003)

$$V(\{\overrightarrow{r_N}\}) = \sum_{bonds} \frac{1}{2} k_b (r - r_0)^2 + \sum_{angles} k_\theta (\theta - \theta_0)^2 + \sum_{torsions} \frac{1}{2} V_n [1 + cos(n\omega - \gamma)] + \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \left\{ 4\varepsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} + \left(\frac{\sigma_{ij}}{r_{ij}} \right)^{6} \right] + \frac{q_i q_j}{4\pi\varepsilon_0 r_{ij}} \right\}$$

Equation 1: Functional Form of OPLS

Lennard-Jones potentials are used to approximate the interactions between two neutral molecules. These potentials take into account the short range Pauli Repulsion forces as well as the long range van der Waals attractive forces from dipole-dipole interactions. Lennard-Jones potentials are able to be transferred from molecule to molecule as they define a single functional group and their non-bonded interactions. They are therefore able to be incorporated into larger more complex molecules that have substituent groups corresponding to those previously defined by the potentials. In the United-Atom force field the transferability of these potentials is known as “transferable potentials for phase equilibria” (TraPPE-UA). (Kamath, Robinson, & Potoff, 2005, p. 46)

Previous Molecular Dynamics Simulations of Polymers

Polymer Collapse

Zhan and Mattice examined simulations of Poly (1, 4-trans-butadiene). Simulations were run to calculate the volumes and densities of this polymer in a vacuum with no periodic boundary conditions and also with periodic boundary conditions in two planes, leaving the third dimension at a large value to represent infinite space. In their findings the polymer exhibited a globular structure when left to equilibrate in a vacuum for 1500 picoseconds. Simulations with periodic boundary conditions in two dimensions forced the polymer into a coil or thin film. They concluded that this was a result of secondary bonding interactions with mirror images of the polymer in adjacent cells. (Zhan & Mattice, 1994)

Temperature Effects on Density in Dense Polymer Systems

The structures and equilibrium properties of dense polyethylene polymer systems through the use of Monte Carlo simulations have been simulated. Employed was a new technique using rigid bonds and bond angles. The range of chain lengths studied were 10-60 carbon atoms long with systems ranging from 3-20 chains. Through simultaneous simulation of a constant volume configurational simulation and an isobaric-isothermal simulation, the most accurate densities of dense polymeric systems were obtained. Lower densities were reported compared to literature when simulating a single chain of polyethylene 60 segments long. Simulations of three polyethylene chains of 60 segments long provided more accurate density data. The simulations of density values ranging from 0-200 degrees centigrade (273-473K) produced a trend that matched the experimental data. The simulations followed the experimental data trend of decreasing density with increasing temperature. (de Pablo, Laso, & Suter, 1992)

The condensed –phase optimized molecular potentials for atomistic simulation studies (COMPASS) force field was used for the molecular systems of myo- and neo-inositol. The study examined the heat of sublimation, density, melting point, and glass transition temperature. The melting point and glass transition temperature plots were defined by cell volume as a function of temperature. Melting point determination utilized system models in the crystalline state, while glass transition temperature determination made use of system models in the amorphous state. Using the plots, the values for these properties were determined by sudden shifts in slope. Values obtained for these properties matched well to experimental data found in literature. (Watt, Chisholm, Jones, & Motherwell, 2004)

Chain dynamics of polymer melts confined to micrometer thick layers were studied. Properties of the polymer melts restricted to the film layer were different than those of the bulk polymer melt. Polymers of molecular weights below the critical value in the confined space were shown to change over from Rouse to reptation dynamics. (Kausik, Mattea, Fatkullin, & Kimmich, 2006) An explicit study of the cross over from Rouse to reptation dynamics in polymers developed a simple model for a one-dimensional chain. The model focused on hernia annihilation and creation which allowed the links of the chain to change between slack and taut. The new model allowed the interchange rate to increase significantly from previous models making the study of the cross-over behavior possible. (Drzewinski & van Leeuwen, 2006)

Branching Effects on Bulk Properties

Rheological properties of polymer melts were studied for polyethylene chains of varying molecular architecture. Linear, star, H-shaped, and comb-shaped structures were used to examine the bulk properties. Branched molecules were found to differ in properties from linear chains of the same molecular weight in the area of viscosity. The study concluded however, that despite the property changes with shape variance, the rheological properties will be most affected by the chain length and degree of branching. (Jabbarzadeh, Atkinson, & Tanner, 2003)

Transferable Potentials for Phase Equilibria United-Atom (TraPPE-UA)

The TraPPE-UA force field was used to model branched alkanes. Lennard-Jones interaction parameters for methine and quaternary carbon groups were added to the model. Critical temperatures and saturated liquid densities were used to optimize these parameters to fit the force field model. The vapor-liquid coexistence curves (VLCC) were then determined for small alkane isomers. Densities were studied using the isobaric-isothermal ensemble. The TraPPE-UA force field was concluded to under predict second virial coefficients, and show small deviations from experimental data of saturated vapor pressures and densities for normal alkanes. The force field also slightly over predicted the critical temperatures of the larger branched alkanes. (Martin & Siepmann, 1999)

The TraPPE-UA force field was extended to include parameters for the functional groups ether, glycol, ketone, and aldehyde. The parameters were optimized using vapor-liquid coexistence curves. Small molecules with the functional groups were simulated for determination of a variety of properties. The simulations resulted in very close fits to experimental data for critical temperatures and normal boiling temperatures. (Stubbs, Potoff, & Siepmann, 2004)

The TraPPE-UA force field was assessed through simulations of carboxylate esters. Partial charges were taken from the optimized potentials for liquid simulations (OPLS) force field. The model was used to determine vapor-liquid coexistence curves, vapor pressures, and critical temperatures, saturated liquid densities, and critical densities of four esters studied. The critical densities and azeotrope of methyl acetate and methanol were both in very close agreement with experimental data. Pure component vapor pressures were over predicted which resulted in the offset of pressure-composition diagrams. The diagrams did show good qualitative trends. (Kamath, Robinson, & Potoff, 2005)

Methodology

Programs

DL_POLY

"DL_POLY is a parallel molecular dynamics simulation package developed at Daresbury Laboratory." (DL_Poly2 user manual)

Input Files

Several input files are needed for the simulations and are described below.

The FIELD file

The FIELD file defines the nature of the molecular forces governing the molecules being modeled. This file contains force field information partitioned into three categories; general information, molecular descriptions, and non-bonded interaction descriptions.

The CONFIG file

The CONFIG file contains the initial coordinates of the molecule. The atom entries of this file with specified coordinates correspond to the FIELD file atom entries, so that together, they construct all the parameters needed to run the DL_POLY simulation.

The CONTROL file

The CONTROL file is responsible for defining the design system parameters and variables. This file specifies the temperature, pressure, timestep, time duration desired for geometry optimization/equilibration, the job time length, etc.

Output Files

The DL_POLY program produces output files from completed simulations described below.

The HISTORY file

"The HISTORY file is the dump file of atomic coordinates, velocities, and forces." (DL_Poly2 user manual) This file contains the coordinates, velocities, and forces at each timestep interval specified in the CONTROL file.

The REVCON file

The REVCON file produces the final atomic coordinates, velocities, and forces. It can be used to restart or continue a simulation. In the current work, the REVCON file is used to assess final geometric configurations along with occupying volume and box volume used in density calculations.

The STATIS file

The STATIS file is a collection of energy data from the simulation recorded for each timestep interval specified in the CONTROL file.

The REVIVE file

The REVIVE file is an accumulation of statistical results and is to be renamed as REVOLD and used as an input if a continuation of a simulation is desired.

The OUTPUT file

The OUTPUT file includes specifications on force fields and simulation control gathered from the CONTROL and FIELD file inputs. This file relays simulation progress, a summary of statistical data which includes the diffusion coefficients, a sample of the final geometric configuration, and radial distribution functions.

DL_FIELD

DL_FIELD is a program designed by Daresbury Laboratory intended to assist in the use of DL_POLY programs. The program creates CONFIG, CONTROL, and FIELD input files for DL_POLY from the user's simple atomic configuration in xyz form. DL_FIELD is able to utilize CHARMm and AMBER force field files in the creation of the input files needed for DL_POLY.

McVol

McVol is a program used in the determination of the volume occupied by a molecule. The program is used in the evaluation of configurational volume to assess changes in volume resulting from shape changes during simulation. The program uses radii of a given distance specified by the user around each atom. In polymer simulations the chains fold in on one another. As this occurs, the radius around each atom becomes slightly overlapped, thus decreasing the calculated volume. A straight chained polymer therefore would have the highest calculated volume.

Visual Molecular Dynamics (VMD)

VMD is a program used to view the simulations. The program converts the data of the HISTORY file of DL_POLY2 into a motion picture of the molecular system.

United Atom Force Field

The united atom method was employed as the program DL_POLY2 could not handle large polymer systems. The computational time required to calculate all required bond energies etc. for each methylene/methyl/methionine group increases as the hydrogen atoms in these groups add to the number of bond angles and dihedrals. These extra attributes dramatically increase the amount of calculations that DL_POLY2 needs to perform and therefore increase computational time excessively to the point where computational chemistry for molecular dynamics purposes becomes senseless. The united atom method groups the carbon hydrogen groups commonly found in the main chain backbone of vinyl polymers. Methyl, methylene, and methionine groups or singular carbon atoms without hydrogen are lumped into one pseudo-atom with a set of its own potentials and parameters. Bond lengths are fixed. Atom mass and charge, angles, dihedrals, Lennard-Jones potentials, and atomic coordinates are still specified. Dihedrals are specified using optimized potentials for liquid simulations (OPLS force) force field data. (Kamath, Robinson, & Potoff, 2005, p. 47)

Force field data known as TraPPE-UA was used for this work. (Kamath, Robinson, & Potoff, 2005, p. 47) (Martin & Siepmann, 1999) (Stubbs, Potoff, & Siepmann, 2004)

Bond	Bond Length, r_0 (A)
CH_x-CH_Y	1.54

Table 4: United-atom transferable potentials for non-bonded interactions

United-atom transferable potentials for non-bonded interactions are shown in Table 4 above. Lennard-Jones potentials and atomic charges for various atoms are specified for non-bonded interactions. Values for Lennard-Jones size (σ) are in angstroms, Lennard-Jones well depth (ε) is in kcal/mol, and partial charges (q) are in units of electron volts. ([a] For sites adjacent to the ether oxygen. [b] For sites adjacent to the alcohol oxygen. [c] For sites adjacent to the aldehyde carbon.)

Non-bonded interactions are described by Equation 2 below, where r_{ij}, ε_{ij}, σ_{ij}, q_i, and q_j are the 'atom' separation, Lennard-Jones well depth, Lennard-Jones size, and partial charges, respectively, for the pair of interaction sites i and j.

$$U(r_{ij}) = 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] + \frac{q_i q_j}{4\pi\varepsilon_0 r_{ij}}$$

Equation 2: Non-bonded Interaction Potential

Lonentz-Berthelot rules were used as shown below in Equation 3 and Equation 4 to calculate van der Waals interactions for other combinations of atoms not specified in Table 4 above. (Kamath, Robinson, & Potoff, 2005, p. 47)

$$\sigma_{ij} = \frac{\sigma_{ii} + \sigma_{jj}}{2}$$

Equation 3: Combining rules for different sizes of Lennard-Jones parameters

$$\varepsilon_{ij} = \sqrt{\varepsilon_{ii} * \varepsilon_{jj}}$$

Equation 4: Combining rules for different well depths of Lennard-Jones parameters

Bond angle bending is controlled by a harmonic potential shown in Equation 5 below. θ is the measured bond angle, θ_0 is the equilibrium bond angle and k_0 is the force constant.

$$U_{angle} = \frac{k_\theta}{2}(\theta - \theta_0)^2$$

Equation 5: Harmonic Potential

Torsional interactions separated by three bonds are described by Equation 6. ϕ is the dihedral angle and c_i are the Fourier constants listed in Table 3.

$$U_{torsion} = c_0 + c_1[1 + cos(\varphi)] + c_2[1 - cos(2\varphi)] + c_3[1 + cos(3\varphi)]$$

Equation 6: Torsional Interaction Potential

(Kamath, Robinson, & Potoff, 2005, p. 48)

Simulations

Parameters

A simulation time for the polymer chains of 1500 seconds was chosen as the minimum run time based on the 1994 paper Molecular Dynamics Simulation of the collapse of Poly(1,4-trans-butadiene) to a globule and to a thin film by Zhan and Mattice. This time duration provides a sufficient time for the system to reach steady state. (Zhan & Mattice, 1994)

The time step of the simulation controls the time value jump between each stepwise calculation. The larger the time step, the faster the simulations are able to reach the desired job end time, but the larger the resulting error in data extracted from the simulation. Larger time steps of 5 fs have been shown to result in dramatic energy drifts. (Izaguirre, Reich, & Skeel, 1999, p. 9853) The time step used for all simulations in the current work was 1 fs.

Various temperatures were used in the simulations of the current work. To assess temperature related trends, simulations of system temperatures ranging from 100K to 800K were used. The extremes were simulated to extrapolate more accurate mid-range temperature data to more clearly show the trends, and not used in explicit value retrieval. Molecular dynamics simulation temperatures have been shown to deviate from actual temperature, (Jobic, Smirnov, & Bougeard, 2001), which is a compounding reason for the broad range of temperatures used in the current work. A far-reaching series of temperatures was used to encompass the entirety of each of the trends examined.

A NVT simulation, known as a canonical ensemble, is based on the temperature and volume of the system having specified average values. A NPT simulation, known as an isothermal-isobaric ensemble, is based on the pressure and temperature of the system having a specified average values, while the volume is able to fluctuate. (Hunenberger, 2005, p. 111)

Polymers

Four polymer types were simulated, straight chained polyethylene or high density polyethylene (HDPE), branched polyethylene or low density polyethylene (LDPE), polypropylene (PP), and ethylene vinyl acetate (EVA). Geometries, coordinates, and force field data (CONFIG and FIELD files) were developed for various lengths of the main chain ranging from 10 pseudo atoms long (a degree of polymerization of 5 – DP of 5) to 5000 pseudo atoms long (a degree of polymerization of 2500 – DP of 2500).

Polymer Chain Length

To assess how chain length affects polymer structure, NVT simulations of each chain length for a given polymer type were run. To isolate the singular molecular chain, the simulations were performed with no periodic boundaries as a single polymer alone in space. This eliminated the possibility of mirror chain interactions between adjacent cells as well as decreased the simulation time. The simulations were run at 300K for 3000 picoseconds to fully reach steady state equilibrium.

Pressure

To determine whether a pressure difference of 1atm changed the density of polymer, two simulations were run for polyethylene with chain lengths of 2000 pseudo atoms. The precursor NVT simulation

equilibrated the 1 chain polymer system for 3000 picoseconds at 300K and 0atm. Following this, the first NPT simulation was run at 0atm for 1500 picoseconds, and the second NPT simulation at 1atm for the same length of time.

Density

To examine the density difference between single and multiple polymers chain systems, a single polymer with a chain length of 2000 pseudo atoms, and four chains of the same length were each run for high density polyethylene and polypropylene. NVT simulations were run for 3000 picoseconds with no periodic boundary conditions to equilibrate the system. NPT simulations were then run for 1500 picoseconds using thermostat and barostat relaxation times of 0.5fs for both. Simulations were run at 300K and 0atm.

Crystallization

Polymer systems of HDPE were simulated at various low temperatures to assess the degree of ordering among the chains. Four chains of 2000 pseudo atoms were examined at temperatures as low as 100K. Systems of 20 chains 500 pseudo atoms in length, 25 chains 200 pseudo atoms in length, and 50 chains 100 pseudo atoms in length were also studied. The chains were initially linear and adjacent with the low temperatures held constant from the beginning of the simulations. Another series of simulations was run where the system of 50 chains 100 pseudo atoms in length was initially equilibrated at 1000K to imitate a liquid polymer melt. The temperature was slowly decreased in each subsequent simulation which was a continuation of the last.

Melting Point

To evaluate the melting point of high density polyethylene and polypropylene, NVT simulations of four chains each of 2000 pseudo atoms in main chain length were run for various temperatures surrounding their respective experimental melting points found in literature. These simulations were run for 3000 picoseconds with no periodic boundary conditions to equilibrate the system. The final geometries retrieved from the REVCON files were then used to start new NPT simulations. These simulations were run for 1500 picoseconds at each respective temperature and at 0atm. The temperatures ranged from 100K to 800k and clustered around the polymer type's experimental melting point.

High density polyethylene polymer systems of a larger number of macromolecules were simulated. Systems of 50 chains 100 pseudo atoms in length, 25 chains 200 pseudo atoms in length, and 20 chains 500 pseudo atoms in length were simulated.

Results

Polymer Structure - Chain Length Effects

HDPE, LDPE, and PP molecules with main chain lengths ranging from 10 to 5000 pseudo atoms long were simulated each for 3000 picoseconds with time steps of 0.01 picoseconds. Each polymer simulation started with a straight chain molecule. Using no periodic boundary conditions, the polymers collapsed in on themselves forming globules.

Globule Formation

Globule formation times were qualitatively extracted through visual methods by viewing the HISTORY output files of DL_POLY using the program VMD. Globule formation was determined to be the initial point of the chain coming together.

A range of HDPE, PP, and LDPE polymer lengths were simulated for 3000 picoseconds at 300K and 0 atm. Figure 6, Figure 7, and Figure 8 below, display globule formation times for various lengths of polymer chains. The plots show a general trend that as the length of the polymer increases, the time to form a globule also increases.

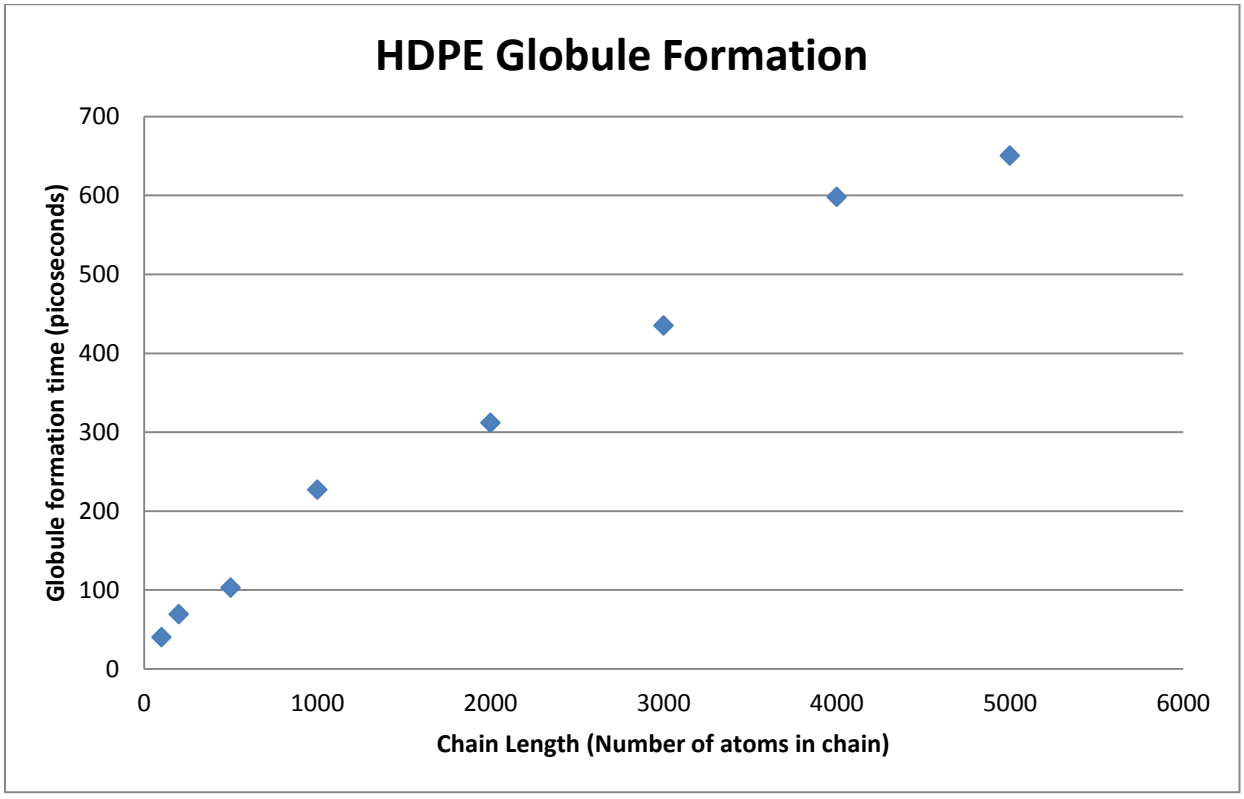

Figure 6: Globule Formation Time of High Density Polyethylene (HDPE) for various chain lengths

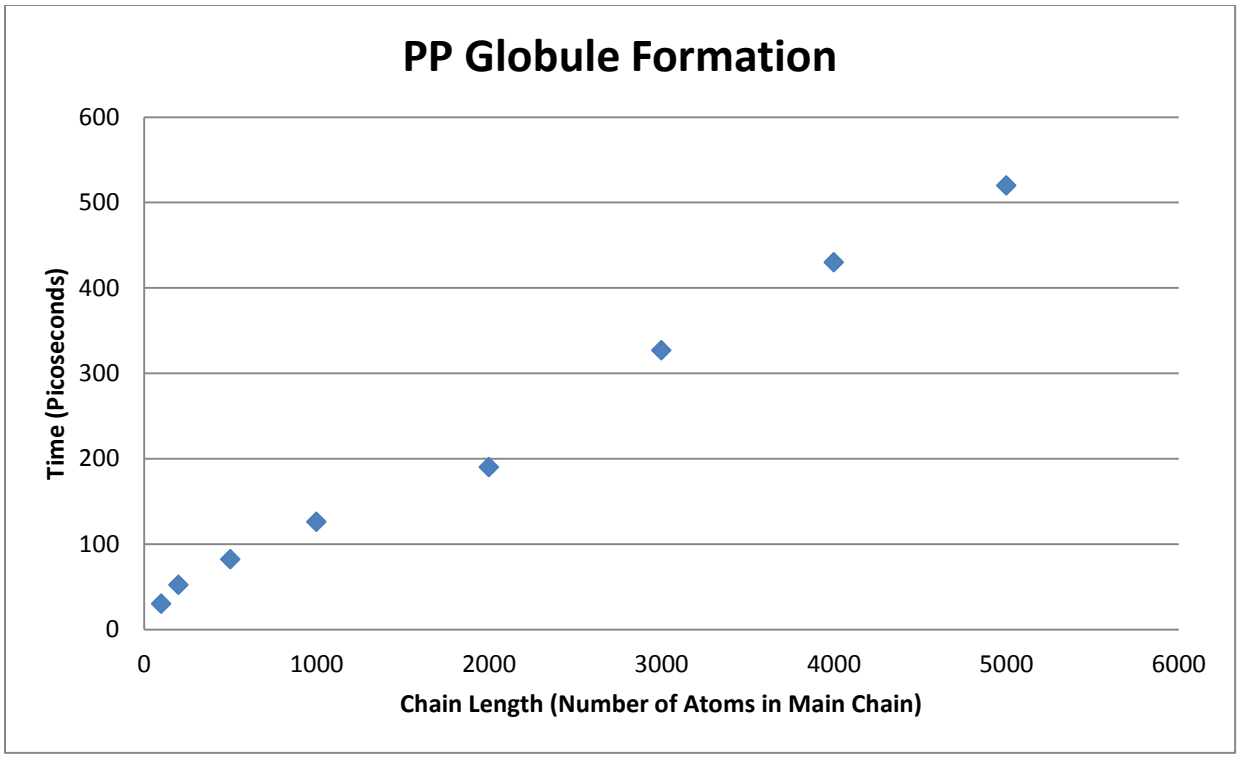

Figure 7: Globule Formation Time of Polypropylene (PP) for various Chain Lengths

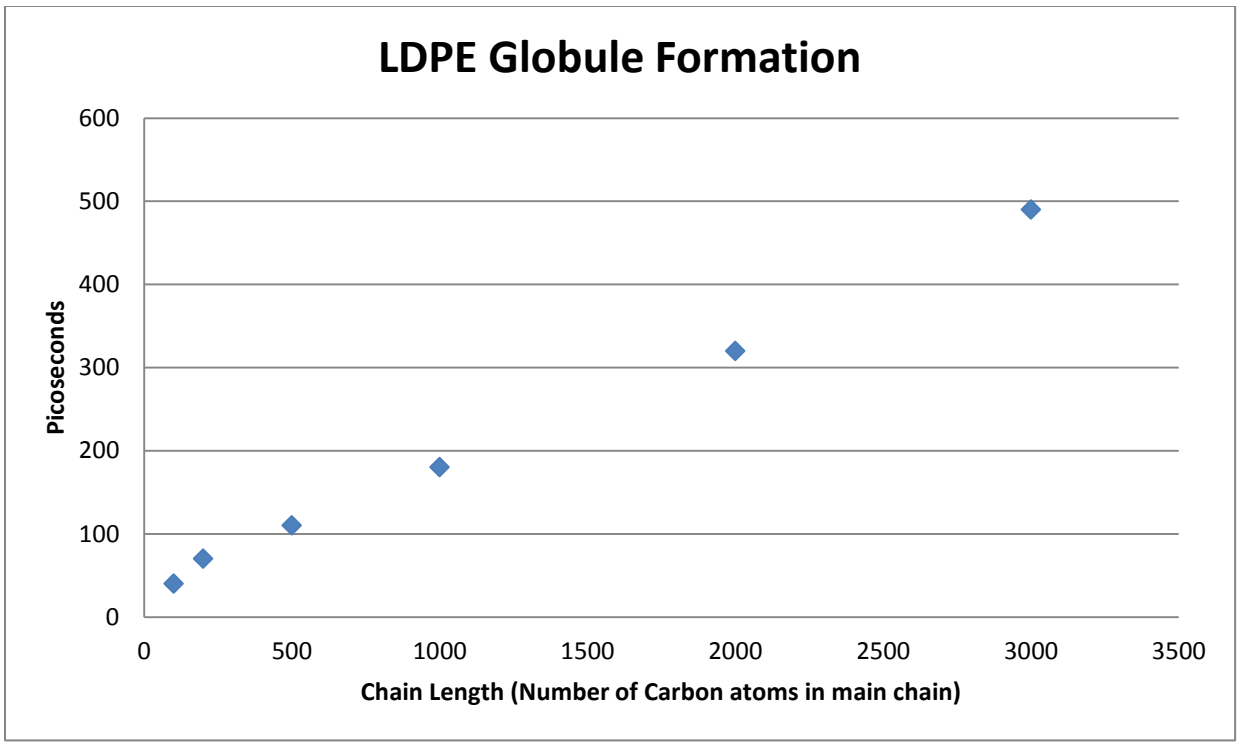

Figure 8: Globule Formation Time of Low Density Polyethylene (LDPE) for various Chain Lengths

Figure 9, Figure 10, and Figure 11 are a different interpretation of the data shown above. The following plots display the globule formation time of HDPE, PP, and LDPE on a per atom basis. The simulations were run at 300K and 0atm for 3000 picoseconds. Each plot levels off and reaches a steady state value. This shows that as the chain length increases over a certain point, the globule formation time on a per atom basis becomes constant.

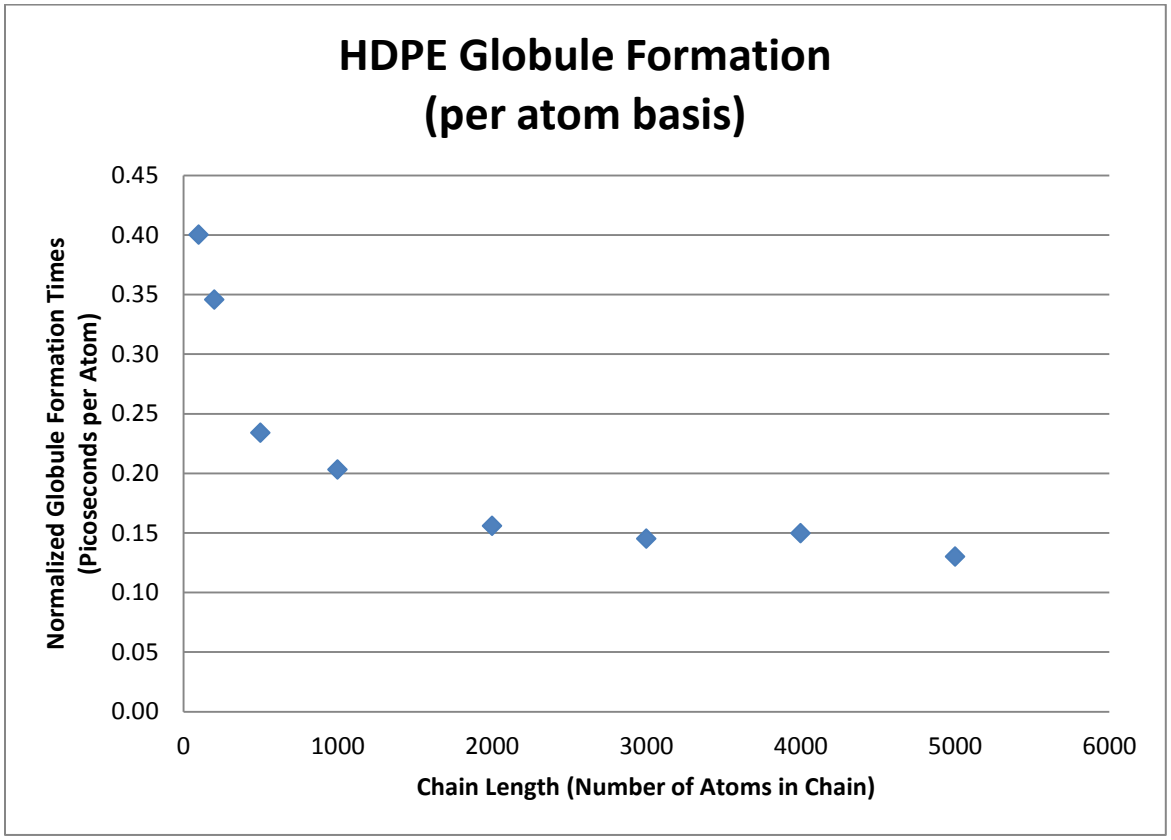

Figure 9: Normalized Globule Formation Time of High Density Polyethylene at various Chain Lengths

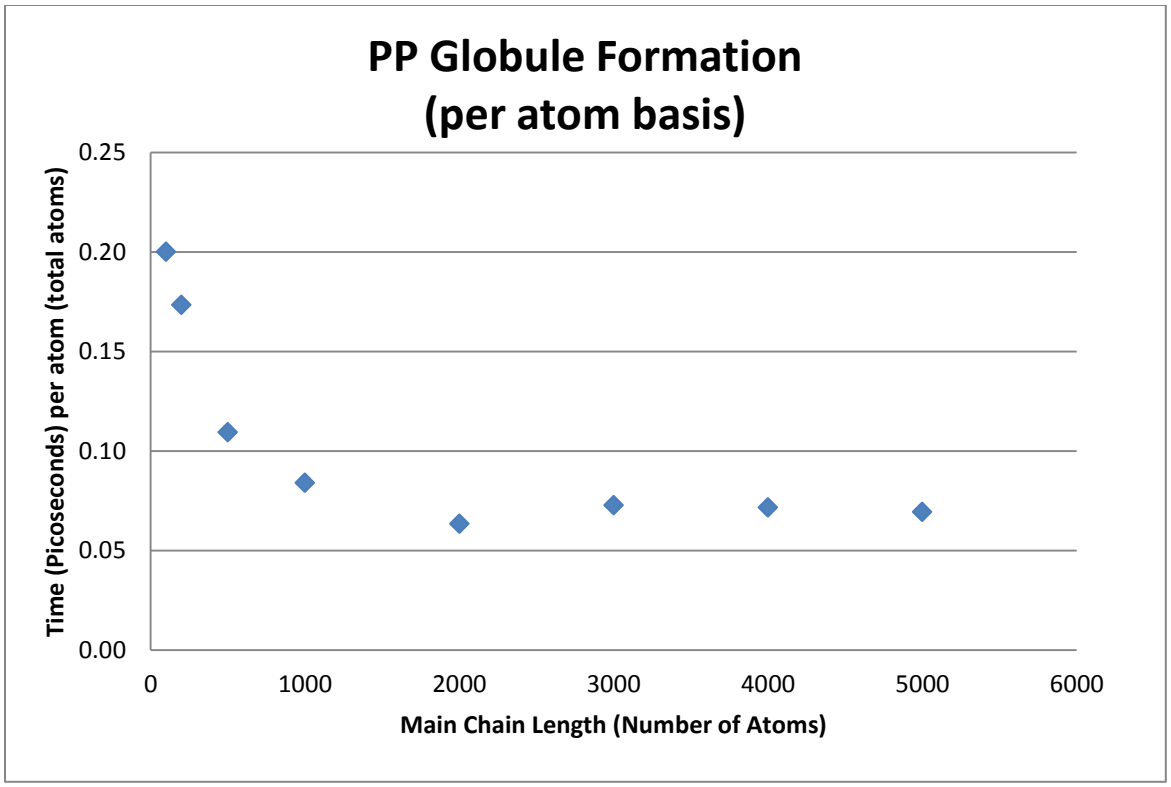

Figure 10: Normalized Globule Formation Time of Polypropylene at various Chain Lengths

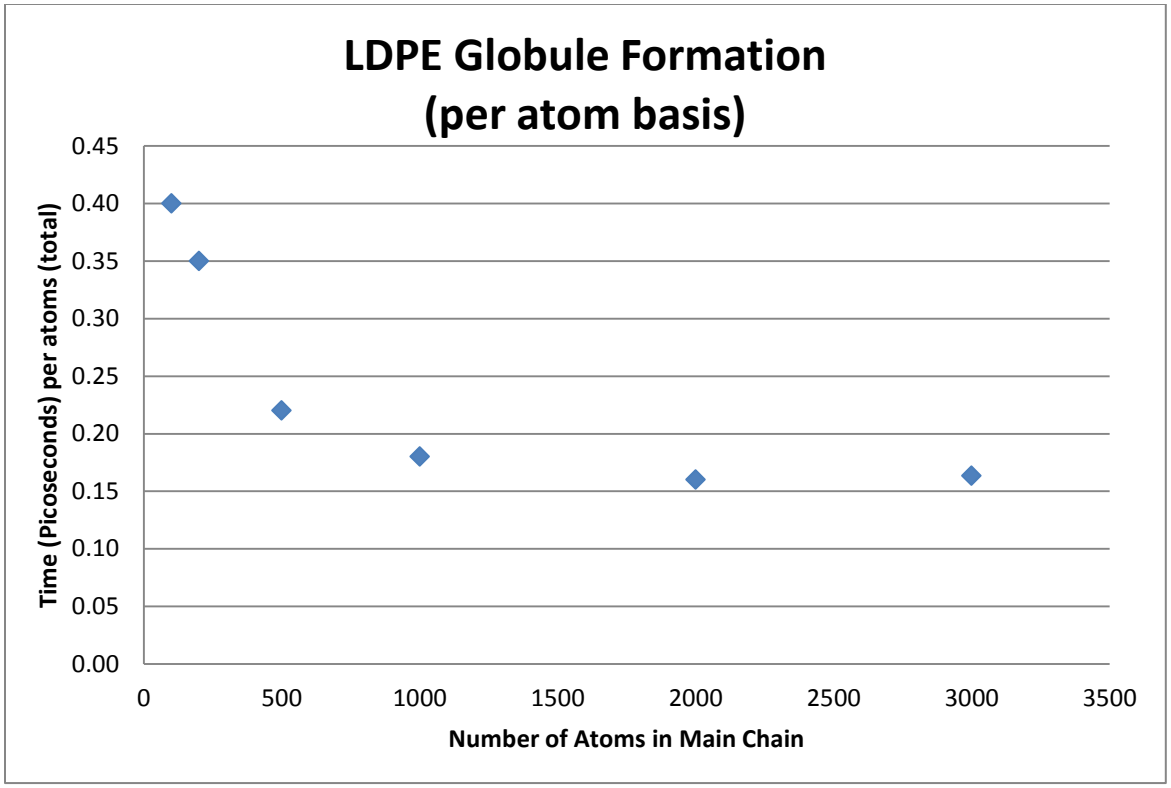

Figure 11: Normalized Globule Formation Time of Low Density Polyethylene at various Chain Lengths

Volume Calculations

The volume occupied by the polymer using a 1.9 angstrom radius around each united atom was calculated using the McVol program. Figure 12 below shows high density polyethylene chains of various lengths simulated with no periodic boundary conditions at 300K and 0atm for 1500 picoseconds. These simulations produced globule-type structures. As the chain length increases, the van der Waals volume increases.

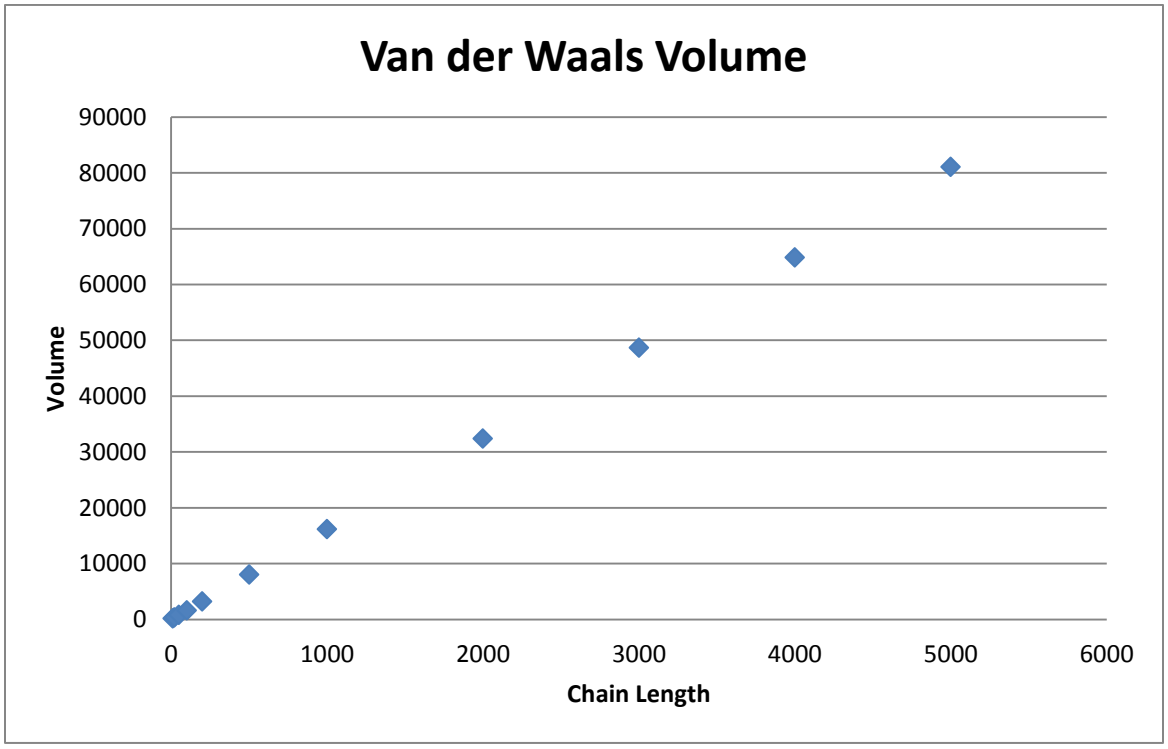

Figure 12: Van der Waals Volume as a function of Chain Length

Figure 13 below, shows the van der Waals volume data for the same set of simulations on a per atom basis. The volume per atom drops significantly as the chain length increases. When the polymer chain becomes a certain length, the volume per atom reaches a constant value.

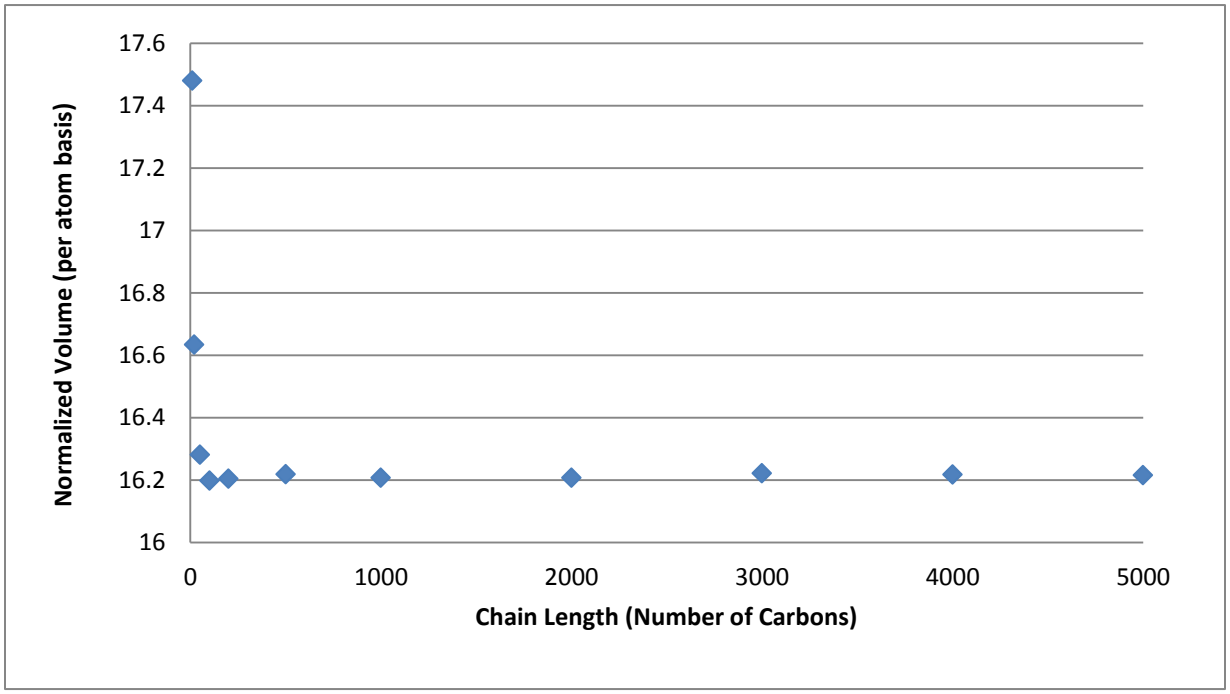

Figure 13: Normalized VDW Volume (per atom basis)

Polymer System Energy

The total system energy of high density polyethylene chains was simulated under no periodic boundary conditions at 300K and 0atm for 1500 picoseconds and was plotted in Figure 14. Globule formation occurred at the intersection of the curved and straight lines. The polymer chains reached a minimum energy state after re-orienting to a globule formation from the straight chain construction established in the initial coordinates. As the chain length increases, a significant initial reduction in energy becomes more and more prominent. Individual energy plots for each chain length can be found in Appendix A. The key to the right of Figure 14 corresponds to chain length in terms of pseudo atoms.

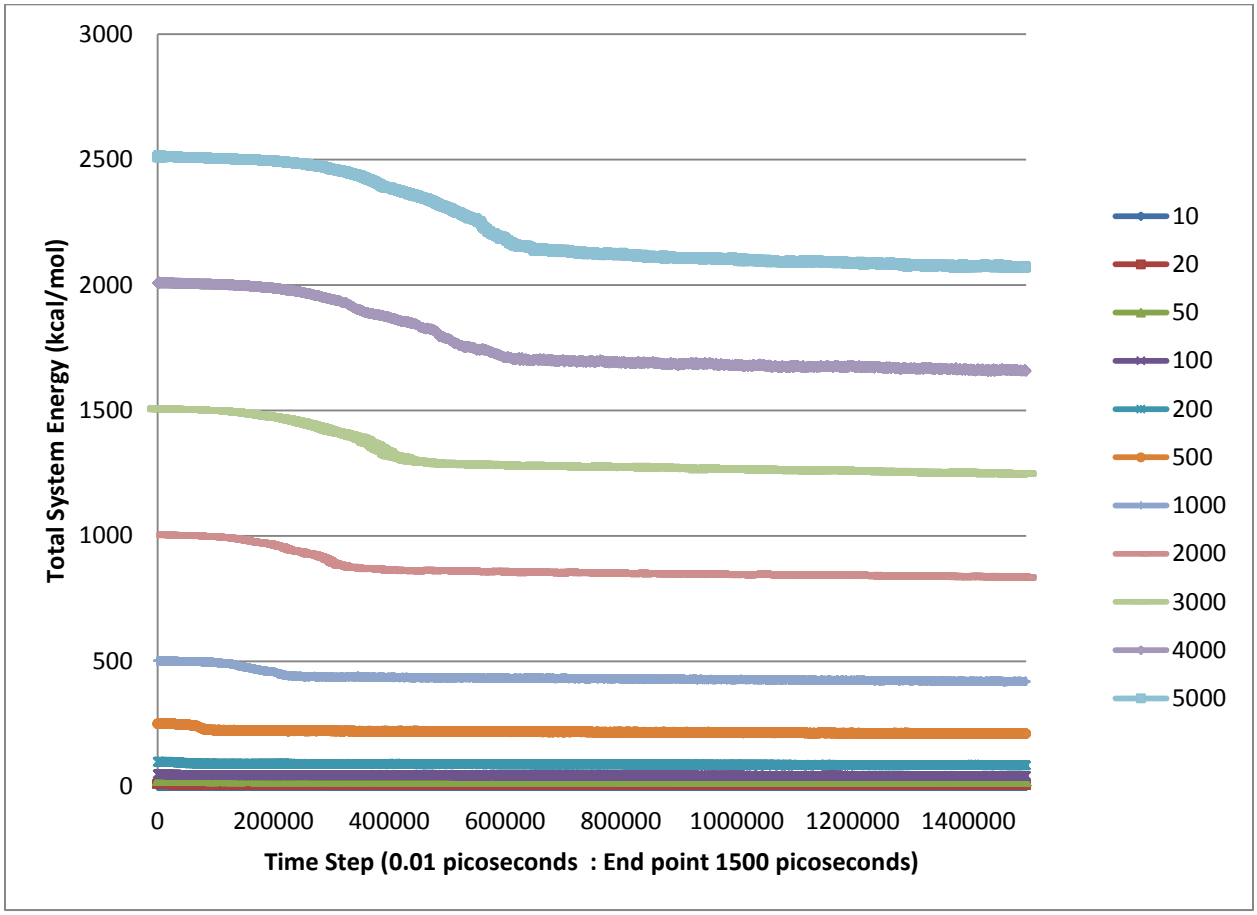

Figure 14: Total System Energy of HDPE for various chain lengths

Polymer Structure - Branching Effects (300K)

Figure 15 below shows the globule formation times of HDPE, PP, and LDPE on a per atom basis. Four chains of 2000 pseudo atoms in main chain length of each polymer type were simulated at 300K and 0atm for 3000 picoseconds. The figure shows a dramatic drop in time per atom between the non-branched HDPE and the side group/branched polymers PP and LDPE.

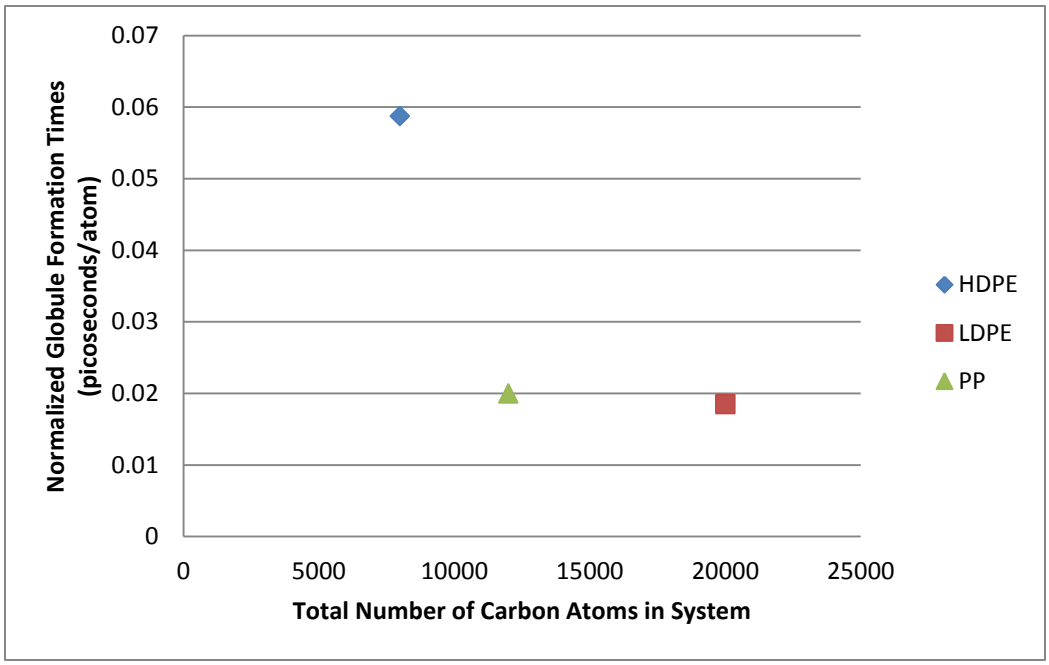

Figure 15: Branching Effects on Globule Formation Time

Figure 16, Figure 17, and Figure 18 are images of HDPE, PP, and LDPE simulations at 130 picoseconds during a 3000 picosecond simulation at 300K and 0atm for each. The scrunching of the chains is more prevalent with increased branching. As branching is increased, the lateral movement of the entire chain is decreased. The straight chains of HDPE show the complete lengths of the chains folding in on themselves to form a globule, whereas the chains of LDPE are seen to climb in on themselves in an elastic-like manner.

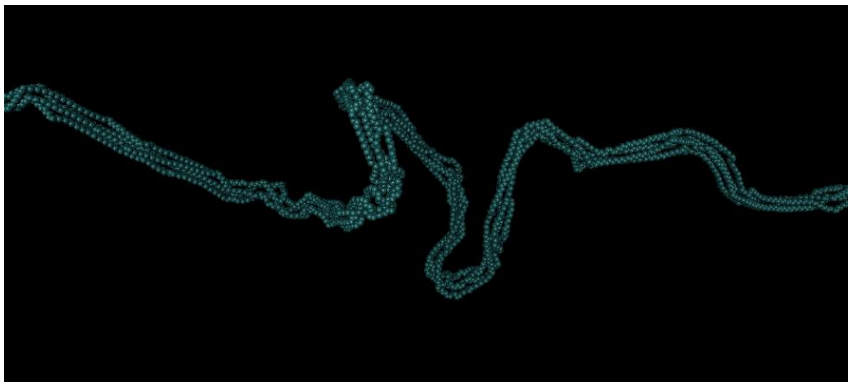

Figure 16: Image HDPE (130 picoseconds)

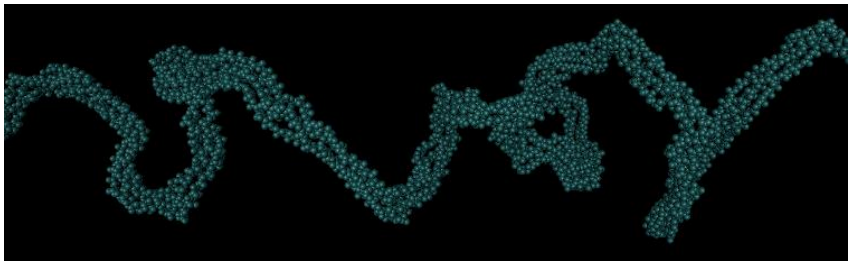

Figure 17: Image of Polyethylene (130 picoseconds)

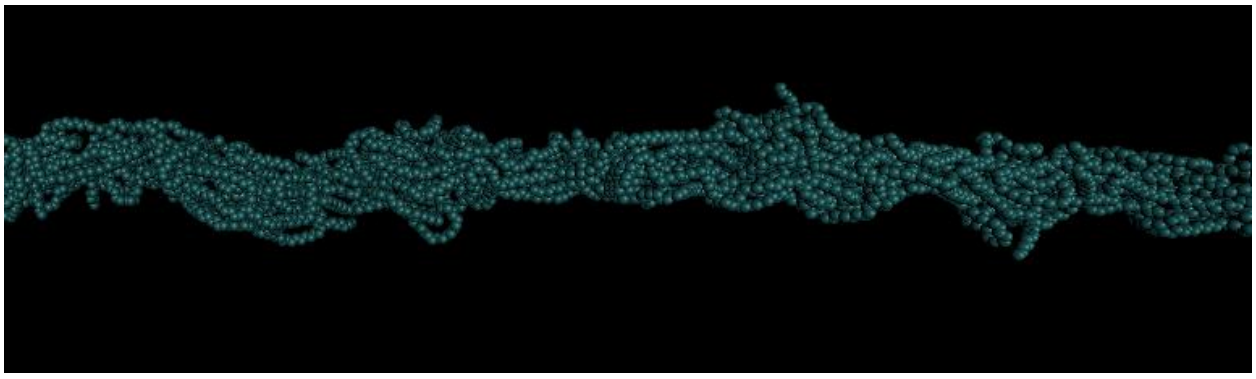

Figure 18: Image of LDPE (130 picoseconds)

Polymer Structure – Temperature Effects

Figure 19 below shows globule formation times for HDPE at various temperatures. The simulations were of four chains of 2000 pseudo atoms run for 3000 picoseconds at 300K and 0atm. As the temperature of the system was increased the time for the polymer to ball up and assume a globule shape decreased.

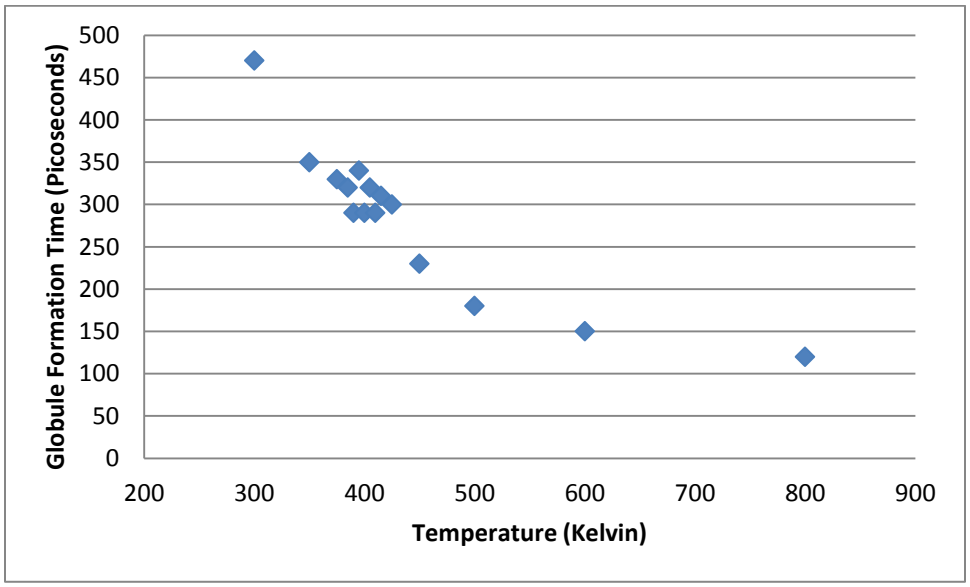

Figure 19: HDPE Globule Formation Times at Various Temperatures

Density

Pressure and Simulation Time Effects

Table 5 below shows the effect of simulation time, pressure, and chain length on the density of the polymer system. Simulations were run for single polymer systems at 300K. Experimental density of HDPE (0% branching; molecular weight 83100 $^{g}/_{mol}$) is 0.947g/cm^3. (Liu, Wang, & He, 2002)

Column	1	2	3	4
Simulation Duration (picoseconds)	150	1500	1500	1500
Polymer Chain Length (Number of Carbons)	1000	1000	1000	2000
Pressure (atm)	0	0	1	0
Temperature (Kelvin)	300	300	300	300
Density	1.0612	0.873	0.867	0.868

Table 5: Density of HDPE

Table 5 above, shows that for different simulation times (column 1 and 2), the longer simulation resulted in the more accurate density calculation. Pressure differences (column 2 and 3) had little effect on the density of the system, although the simulation with 0atm pressure was closer to literature values. The length of the polymer chain (columns 3 and 4) also had an insignificant effect on the density of the system.

Chain Length and Number of Chain Effects

Simulations shown in Table 6 were run for 3000 picoseconds at 300K and 0atm. Table 6 displays the density data for simulations of different chain lengths and quantities. Despite the previously stated findings of the critical molecular weight being 2000 carbons long for HDPE (Figure 6), the simulations of the chains of 100 and 200 pseudo atoms long produced the most accurate density data.

Number of Chains	**1**	**4**	**25**	**50**
Chain Length – Number of Atoms	2000	2000	200	100
Density (g/cm3)	0.868	0.886	0.951	0.944

Table 6: HDPE density data for different chain lengths and number of chains

Figure 20 and Figure 21 below, are images of HDPE for a 50 chain system of 100 pseudo atoms long and a 20 chain system of 500 pseudo atoms long respectively. The images were taken during 3000 picosecond long NPT simulations at 300K and 0atm. Voids can be seen in Figure 21 in the simulation of a longer chain system of lesser quantity.

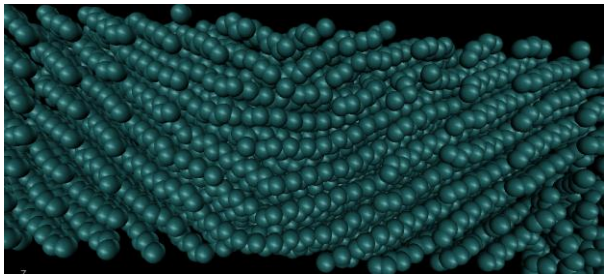

Figure 20: Image of HDPE 50 Chain System (100 atoms long)

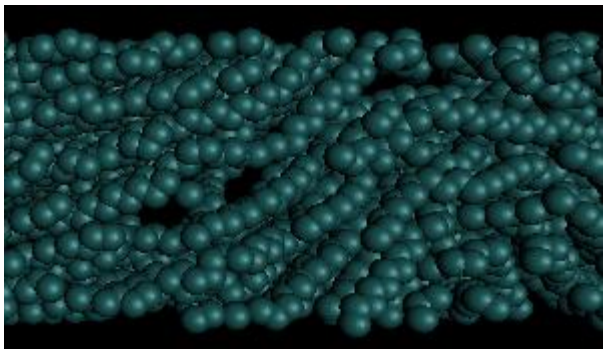

Figure 21: Image of HDPE 20 Chain System (500 atoms long)

Equilibration Effects

Initial NVT and NPT simulations in Table 7 were run for 3000 picoseconds at 300K and 0atm. Subsequent continuation simulations (NPT post equilibration) were run for 1500 picoseconds at 300K and 0atm. Table 6 Table 7 displays the results of six simulations that assessed the effects of equilibrating the system before running a NPT simulation to calculate the density. Equilibration is shown to affect the density minimally.

Type of Simulation	NPT - (no NVT equilibration	NPT – (with NVT equilibration
HDPE 50 Chains – 100 atoms long	0.942	0.944
HDPE 25 Chains – 200 atoms long	0.948	0.951

Table 7: Equilibrium/non-equilibrium HDPE density values (g/cm3)

Branching Effects

Densities of HDPE, PP, and LDPE are shown in Table 8. Simulations were performed for four chain systems at 300K and 0atm for 3000 picoseconds. A general trend can be seen where density increases with decreasing branching.

Polymer Type	HDPE	PP	LDPE
Density (g/cm3)	0.886	0.845	0.734

Table 8: Density of Four Chain Polymer systems (main chain length 2000 atoms)

Crystallization / Melting

A series of simulations were run at various temperatures under no periodic boundary conditions. Four chains of HDPE with chain lengths of 2000 pseudo atoms comprised each system. Each simulation was run at 0atm for 3000 picoseconds.

Figure 22 and Figure 23 below show a low temperature simulation which resulted in the polymer chains aligning themselves into ordered structures.

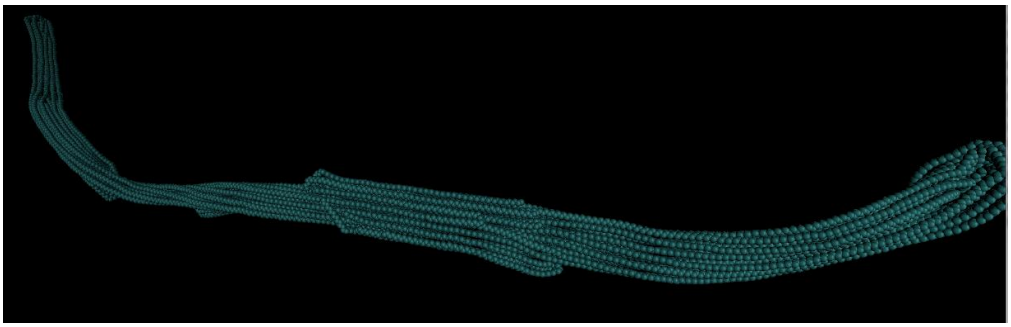

Figure 22: Image of HDPE 100K (3000 picoseconds)

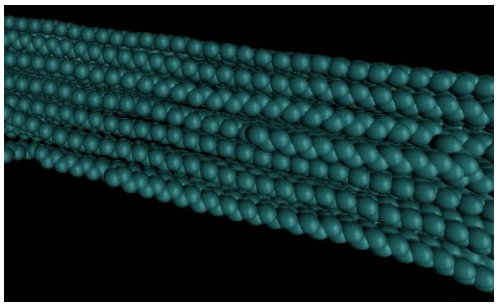

Figure 23: Image of HDPE 100K enlargement (3000 picoseconds)

Figure 24, Figure 25, and Figure 26 show room temperature simulations at 300K. These resulted in the formation of a globular structure. The chains stayed together in the globule formation process as seen in Figure 25.

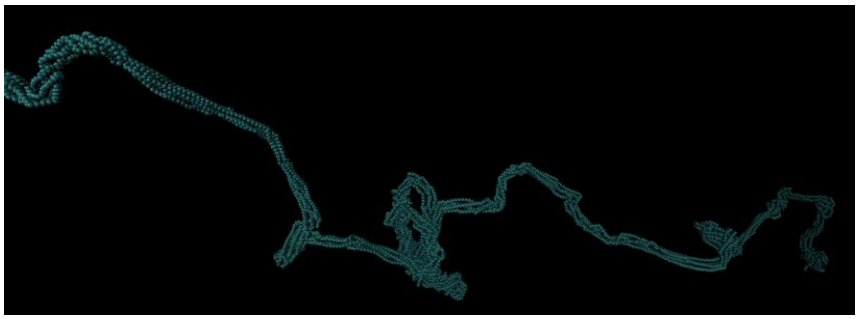

Figure 24: Image of HDPE 300K (220 picoseconds)

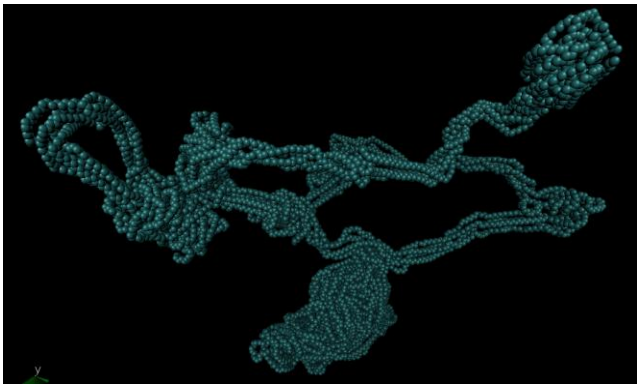

Figure 25: Image of HDPE 300K (340 picoseconds)

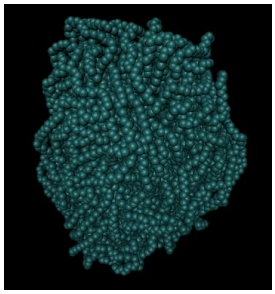

Figure 26: Image of HDPE 300K (3000 picoseconds)

As the temperature starts to increase, the chains do not stay together as well as seen by the large chain separation in Figure 27. Figure 28 and Figure 29 show singular chains stemming out from the globule which have parted from group of four from which they started.

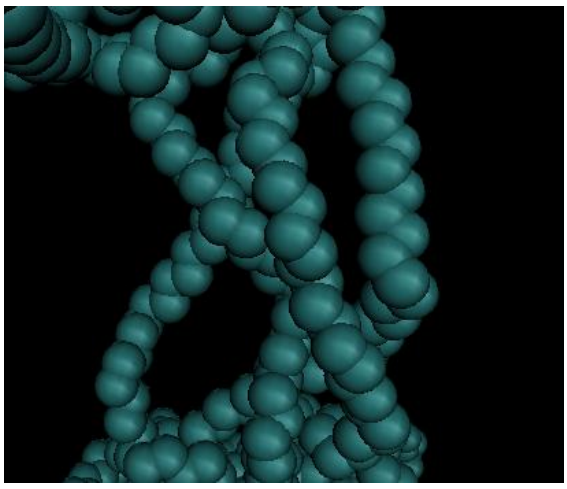

Figure 27: Image of HDPE 500K (130 picoseconds)

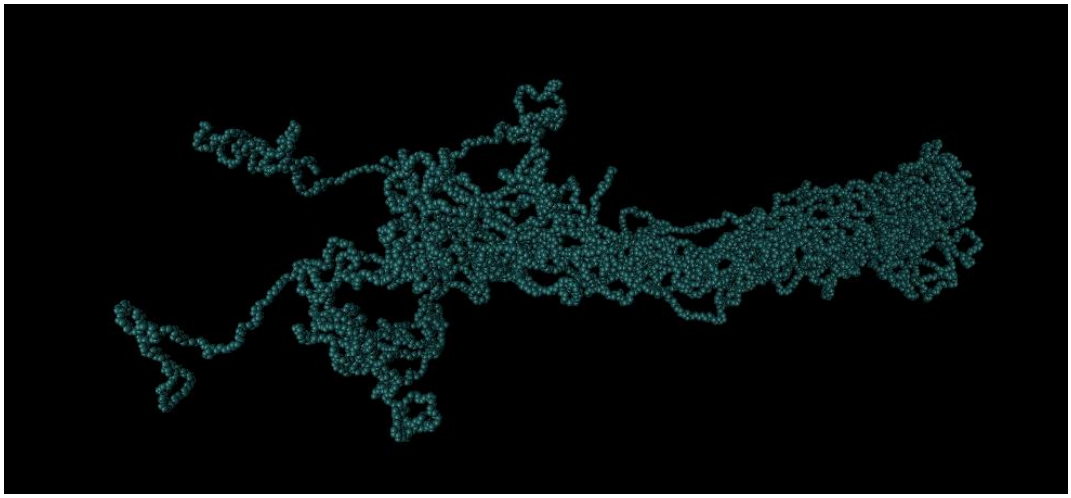

Figure 28: Image of HDPE 800K (210 picoseconds)

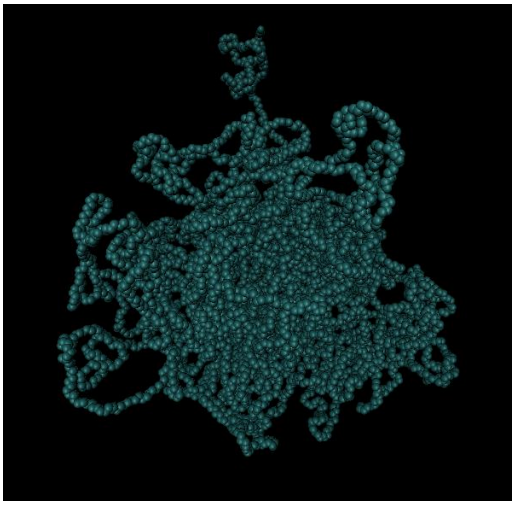

Figure 29: Image of HDPE 800K (3000 picoseconds)

Melting Point Determination

Density data for HDPE and PP at various temperatures are shown in Figure 30 and Figure 31 below. Four chains of 2000 pseudo atoms in length were simulated (NVT) for 3000 picoseconds with no periodic boundary conditions to equilibrate the system and then run (NPT) for an additional 1500 picoseconds. The pressure for all simulations was 0 atm. The melting point/glass transition temperatures were estimated by the vertical dotted lines placed between the two density values of differing slopes. The glass transition temperature is estimated for HDPE in Figure 30 as the system is mostly amorphous, while the melting point is estimated for PP in Figure 31 as the system is more crystalline.

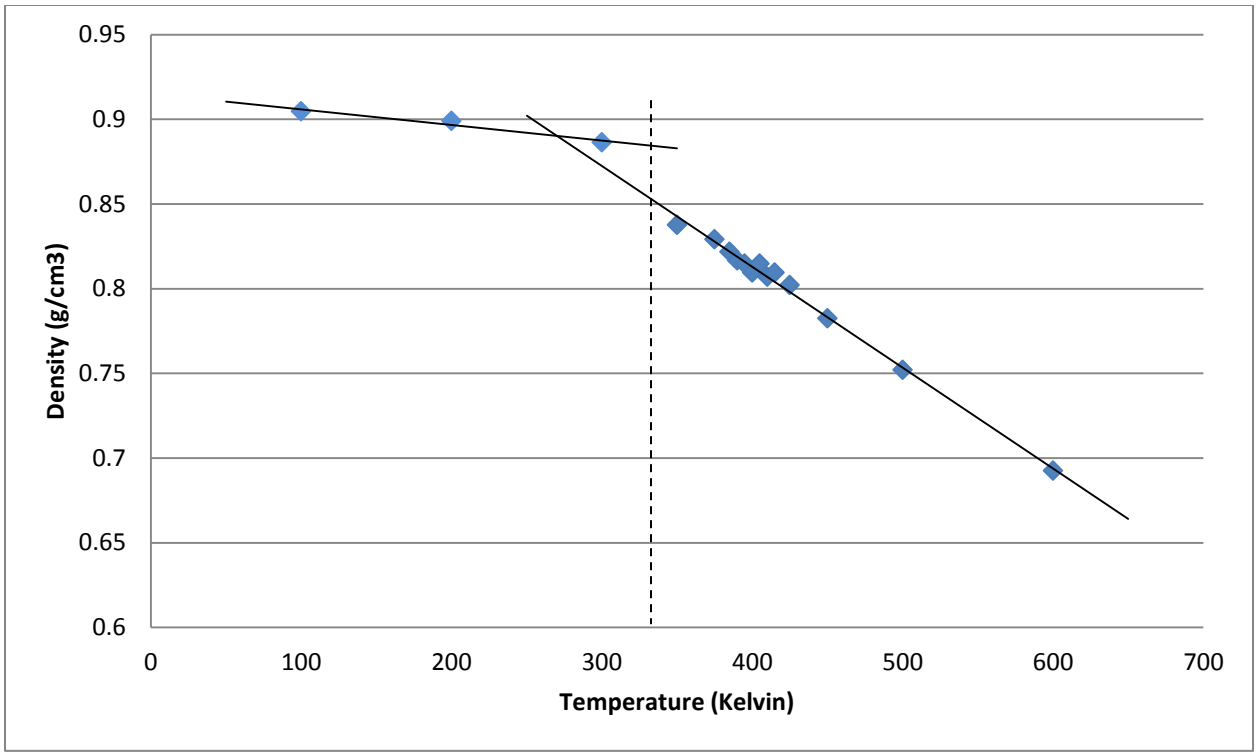

Figure 30: Density of HDPE at various temperatures

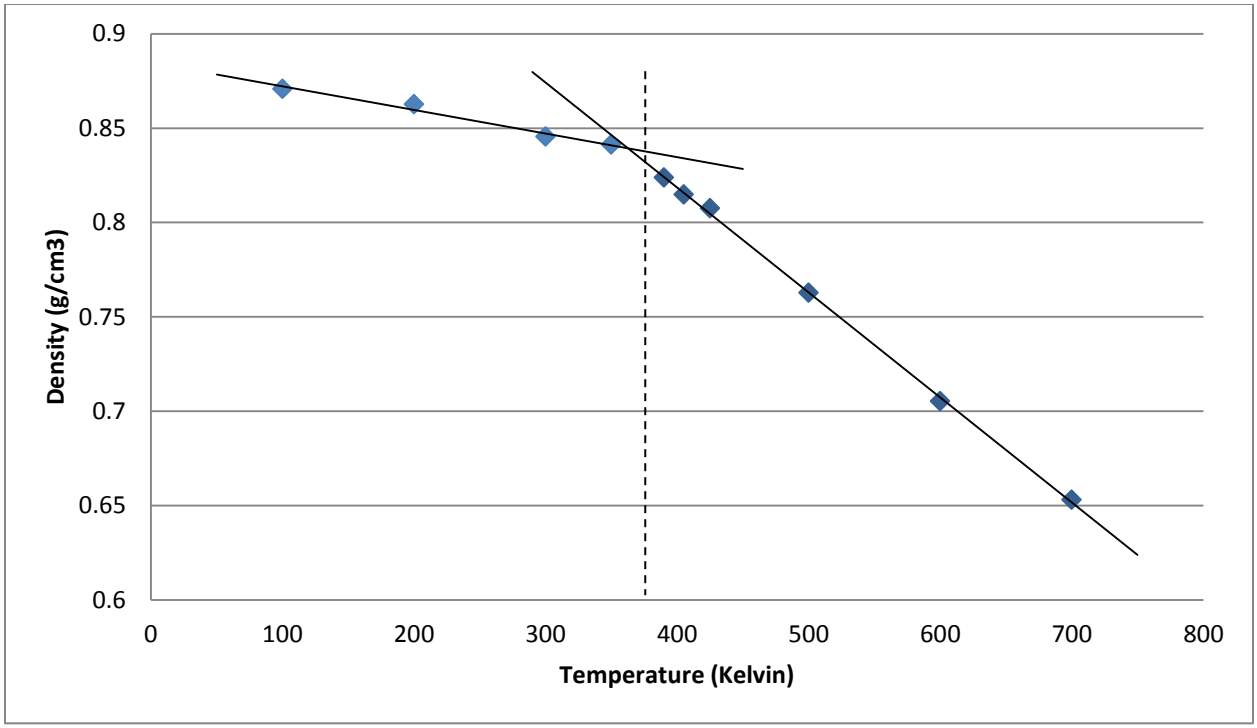

Figure 31: PP Density Data at Various Temperatures

Figure 32 below shows the volume data for polypropylene extracted from Figure 31. The plot shows a change in expansion rate of the polymer system when plotted for various temperatures.

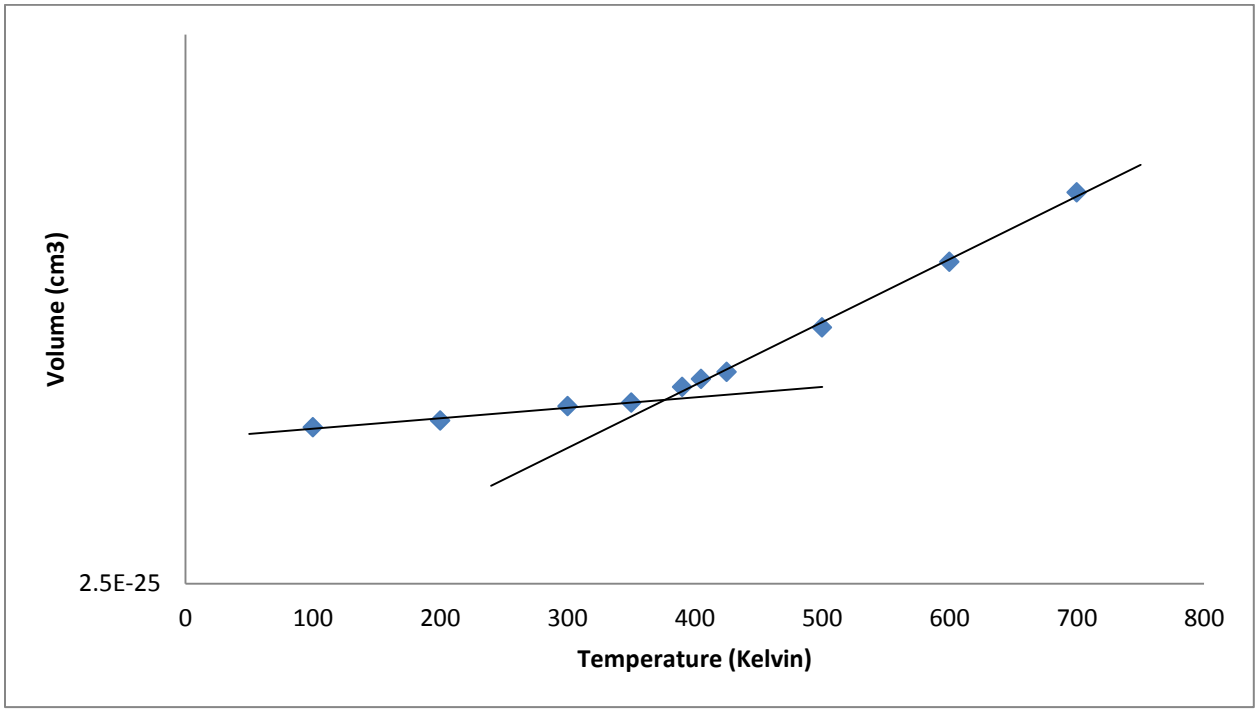

Figure 32: PP Volume data at various temperatures

Four chains of HDPE and PP were simulated for 3000 picoseconds at 0 atmospheres for various temperatures around the respective melting points of each polymer. Figure 33 and Figure 34 below, show the configurational energy change with increasing temperature. Figure 35 and Figure 36 below, show the van der Waals forces plotted against temperature. A slight inflection point can be seen around the melting temperatures of each polymer for these two types of system energy.

Discussion

Globule Formation

As the time values were visually determined they are therefore approximate. The CONTROL file specifies the number of steps recorded to the HISTORY file. In order to keep the HISTORY file to a reasonable size, the steps logged were taken every X amount of steps. For longer simulations, this number increased. For a three million step simulation, steps recorded every 10,000 steps would produce 300 entries in the HISTORY file. Depending on the fraction of steps recorded, the instant that the globule may have appeared to form could possibly be some time after the actual formation. The globule formation times were used to assess trends and should not be taken as exact formation times.

Exact globule formation times could be more accurately determined through recording a larger percentage of the simulation steps. Using the coordinates of the HISTORY file, the McVol program could also be employed to calculate the volume of the molecule at every step. A more exact globule formation time could then be extracted based on the volume change. This would be a very tedious and time consuming process, and so was not used for the general purposes of this work.

The energy data was referenced when determining the globule formation times. The intersection of the curved dramatic energy drop with the linear, such as seen in Figure 14, also describes the globule formation time. The values extracted from the energy graph such as this were on the same level of accuracy as visual interpretation.

Figure 6, Figure 7, and Figure 8 display the globule formation times at various chain lengths. As chain length increases, so does the time it takes to form a globule. This is expected as the ends of long chains are further from each other than the ends of short chains, and so will take longer to come together as there is a greater distance to travel.

Figure 9, Figure 10, and Figure 11 display the globule formation times on a per atom basis. These plots show that as the size of the chain increases, the globule formation times on a per atom basis achieve constant values. When a constant value is reached, the van der Waals forces act proportionally on each atom in the polymer. This means that there is a minimum chain length for the van der Waals forces to be consistent. The minimum chain length corresponds to the critical molecular weight of a polymer.

The critical molecular weight values extracted from the plots were approximately 2000, 1700, and 1500 pseudo atoms long for HDPE, PP, and LDPE respectively. As HDPE is the most flexible out of the polymers tested, it is expected that the critical molecular weight will be highest, and therefore the chain length will be longest as it does not have side groups. The side groups of polypropylene stiffen the chain making it more rigid, promoting entanglement and van der Waals attractive forces. The branching of LDPE entangles the chain to an even higher degree, promoting van der Waals attractive forces also. As a result, polymer chains of 2000 pseudo-atoms long formed the standard chain length for all subsequent simulations in this work.

Figure 15 shows the effects of branching on globule formation time. The plot shows that globules are formed much more quickly when the chains have any amount of side groups or degree of branching.

The dramatic drop in time from the HDPE to the fairly equal values of both polypropylene and LDPE demonstrates this. The HDPE molecules are able to slide over one another more easily than the branched molecules do. The branching helps promote quicker globule formation due to increased entanglement of the chains.

Volume

The volume on a per atom basis shown in Figure 13 reaches an asymptotic value as the chain length increases beyond a certain point. The van der Waals forces from other parts of the chain promote bond angle bending to wrap the polymer in tightly and form a globule. The straight chain volume is larger than the volume of the globule. This can be seen as the shorter chains have larger volumes and are not able to collapse in on themselves to form globules but instead remain quite straight. The spheres encompassing each pseudo atom have large radii as specified by the McVol program. These radii are able to overlap and do so when attractive van der Walls forces bring distant parts of the chain together. The folding and tangling process promotes overlapping and therefore a decrease in volume. As bond angles can only vary so much, shorter chains are not able to exhibit McVol radii overlap, and therefore display a larger volume per atom.

Energy

The total system energy plot of HDPE, Figure 14, shows that as the chain length increases, the difficulty in maintaining a linear chain also increases. The energy needed to keep the polymer chain in this straight state is much higher and so becomes increasingly less ideal. This is described by the initial dramatic energy drop followed by the steady state straight line with minimal slope. The straight chain reaches a much lower energy state upon formation of a globule which occurs at the end of the dramatic energy drop. The globule undergoes a steady state energy minimization as it reorients itself to find the most stable conformation. This reorientation is described by the straight part of the line with minimal slope on the energy plot.

Density

The results in Table 6 show that the number of chains simulated is more important than the length of chain. The more chains that are simulated, the closer the density becomes to the actual value. The shorter polymers with the larger number of simulated chains were able to fill the simulation box more thoroughly as seen in Figure 20, depicting a more accurate polymeric environment with more precise bulk properties. The 1 and 4 chain systems may have created voids within the simulation box due to a large degree of chain folding, which resulted in a decreased density.

The results from Table 8 show an accurate trend. HDPE has a higher density than LDPE. The side groups and branching do not allow adjacent chains to lie as closely to one another as would linear chains. The inefficient packing results in voids within the system, effectively lowering the density.

Crystallization/Melting

Qualitative observations of crystallization and melting were made when running simulations at various temperatures.

Figure 22 and Figure 23 show crystallization. Four polymer chains were initially simulated at 100K for 3000 picoseconds. The figures reveal that the chains folded over onto one another in an ordered manner multiple times.

Figure 28 and Figure 29 depict melting as there are singular chains extending out from the center. The increased energy in the system has overpowered the attractive van der Waals forces allowing the chains to move independently. Only the bulk of the globule has enough mass to keep the chains centered in a globule type sphere, but they are held together much less tightly than the globules simulated at lower temperatures.

Melting Point/Glass Transition Temperature Determination

Figure 30 and Figure 31 show the densities of HDPE and polypropylene respectively as a function of temperature. Two lines were drawn on each figure that represented the general sloped trend of the data. A third dotted line was drawn in the middle of the two density values at the intersection of the two previous lines. This dotted line describes the melting points for crystalline systems and the glass transition temperatures for amorphous systems. Both systems were comprised of four chains and could be described to have portions of both crystalline and amorphous. As mentioned earlier, the temperatures of molecular simulations may not correspond perfectly to those in the lab. (Jobic, Smirnov, & Bougeard, 2001) For this added reason, the current work is more interested in the qualitative results produced by the simulations. The 'melting point' therefore of polypropylene is seen to be higher than that of HDPE which is expected. The methyl side groups of polypropylene act as barriers that hinder chain slippage and promote entanglement.

The intersection of the two lines with the dotted line describes the breaking point of the attractive van der Waals forces. Figure 32 displays the volumes of PP at various temperatures and can be thought of as the distances between neighboring molecules. This plot demonstrates how the VDW forces have a certain distance where the attraction is fairly consistent. When adjacent molecules exceed this distance, the attraction diminishes quickly, as seen by the rapid volume expansion, and therefore rapid separation of adjacent chains.

The melting point values for both plots are lower than literature values. These simulations were performed with four chains of 2000 pseudo atoms in length. As mentioned earlier in regards to density, simulations with larger numbers of molecules proved to be more accurate. As the melting points were calculated via a density change method, simulations with larger numbers of molecules may provide more precise results.

Figure 33 and Figure 34 show the configurational energy of a four chain system of HDPE and PP respectively. Figure 35 and Figure 36 show the van der Waals attractive forces of the same HDPE and PP systems. The slight inflection point shows the energy change corresponding to chain slippage or melting. The inflection point may have been more defined if simulations of a larger number of polymers were used.

Conclusions

The phenomenon of crystallization was qualitatively observed in the low temperature simulations. Chains were seen to form ordered structures through folding. Melting was also qualitatively observed at high temperatures. Chains were seen to separate from the four adjacent chains from which they initially started.

In agreement with Zhan & Mattice, globule formation was seen in all polymers simulated at temperatures at and above 300K. This depicted van der Walls attractive forces as a result of dipole-dipole interactions. As temperatures increased the chains were seen to break away from the central globules, showing that the increased energy of the system overpowered the attractive forces.

Physical properties were seen to differ between polymers of branched and linear structures. This was in accordance with the findings of Jabbarzadeh et al. The trend of critical molecular weights of all polymers modeled was accurately predicted. Polymers with the least branching exhibited the largest values, while polymers with the most branching displayed the lowest values.

The TraPPE-UA force field did accurately predict the density of high density polyethylene at room temperature, when simulated with a large number of chains. The simulations with four chains at and over the critical molecular weight had densities that deviated from experimental data more so than much shorter chains simulated with a large quantity. The density values corresponded to experimental data. This concludes that the number of chains in the simulation is more important than the length of the chains when studying density of a polymeric system. The current work used longer polymer chains and a larger number of chains during density simulations and expectedly reported densities more accurate than those of de Pablo et al.

Various accurate polymer property trends were observed in the current work. It is concluded that the same trends can be witnessed with a wide variety of polymer systems including those of special interest to the running shoe industry. Careful considerations need to be made in choosing how to model polymer systems of importance. Optimizations of these design parameters will produce more accurate data for predicted properties. Exploration of other force fields not used in this work may provide more precise values for both the properties examined in this work and other properties useful in assessing running shoe polymers.

Total System Energy Plots for HDPE of Various Chain Lengths

Figure 37 through Figure 47 show the total system energy of HDPE at various chain lengths. Simulations were performed at 0atm and 300K for 1500 picoseconds. All figures in this appendix have Y-axis energy units of kcal/mol and X-axis units of time steps (0.01 picoseconds, where the end point time is 1500 picoseconds).

Appendix B

Branching Effects of Polymer Structure

Low Density Polyethylene (LDPE)

Figure 48 through Figure 51 below, were images taken from one simulation of LDPE. Four chains of 2000 pseudo atoms in length were simulated at 0atm and 300K for 2000 picoseconds. The figures show the entanglement effects of the branching as the polymer chains form a globule over time.

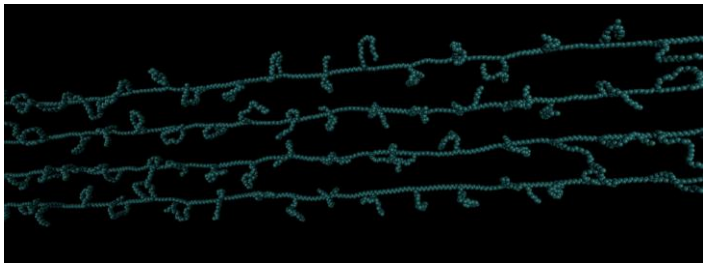

Figure 48: LDPE Initial Structure (Four Chains with Main Chain Length of 2000 pseudo atoms)

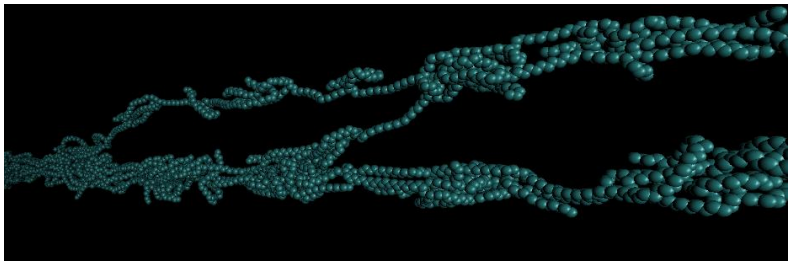

Figure 49: LDPE (60 picoseconds) (Four Chains with Main Chain Length of 2000 pseudo atoms)

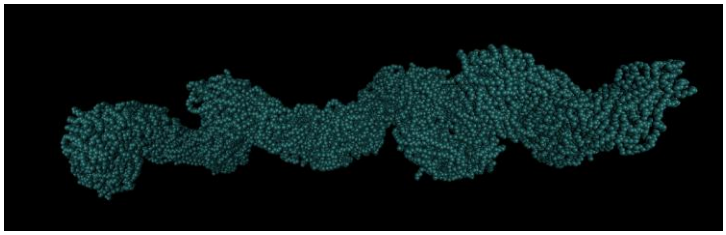

Figure 50: LDPE (310 picoseconds) (Four Chains with Main Chain Length of 2000 pseudo atoms)

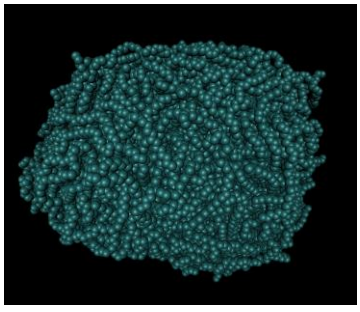

Figure 51: LDPE (2000 picoseconds) (Four Chains with Main Chain Length of 2000 pseudo atoms)

Polypropylene (PP)

The figure below was an image taken from one simulation of PP. Four chains of 2000 pseudo atoms in length were simulated at 0 atm and 300K for 3000 picoseconds. The figure shows the four straight adjacent chains beginning to interact. This demonstrates the attractive van der Waals forces.

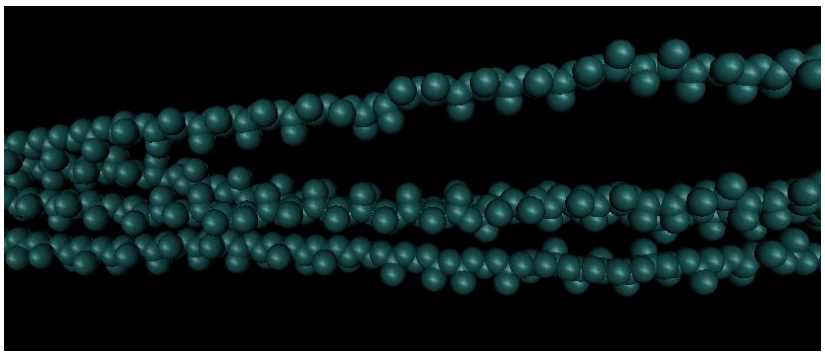

Figure 52: PP Initial Structure (Four Chains with Main Chain Length of 2000 pseudo atoms)

Appendix C

Final HDPE Temperature Variation Geometries (3000 picoseconds)

Figure 53 through Figure 60below, show four polymer chains of 2000 pseudo atoms long at various temperatures at 3000 picoseconds. The NVT simulations were run with no periodic boundary conditions at 0 atm. The progression of temperatures ranges from 100K to 800K.

Appendix D

Density Calculations

Sample calculations are provided that detail how the box size values from the simulations were used to find the polymer density. Lengths of the X, Y, and Z sides of the simulation box were extracted from the REVCON file of completed NPT simulations.

Conversions

$1\ atomic\ mass\ unit = 1.6605389217 * 10^{-30} grams$

$1\ picometer = 10^{-10} centimeters$

$HDPE\ 1000 = 14028.95594 amu$

$Polymer\ Mass = (14028.95594 amu * 1.6605389217 * 10^{-30} g) = 2.32956274 * 10^{-26} grams$

$HDPE\ 2000 = 28057.91188 amu$

$Polymer\ Mass = (28057.91188 amu * 1.6605389217 * 10^{-30} g) = 5.3646 * 10^{-26} grams$

$$Density = \frac{mass}{volume}$$

Single Chain Simulations

150 Picosecond Simulation, 0atm, HDPE1000, 300K

$Polymer\ Volume = (28 * 10^{-10} cm)^3 = 2.1952 * 10^{-26} cm^3$

$$Density = \frac{2.32956274 * 10^{-26} grams}{2.1952 * 10^{-26} cm^3} = 1.061 \frac{g}{cm^3}$$

1500 Picosecond Simulation, 0atm, HDPE1000, 300K

$Polymer\ Volume = (29.8827 * 10^{-10} cm)^3 = 2.66845267 * 10^{-26} cm^3$

$$Density = \frac{2.32956274 * 10^{-26} grams}{2.66845267 * 10^{-26} cm^3} = 0.873 \frac{g}{cm^3}$$

1500 Picosecond Simulation, 1atm, HDPE1000, 300K

$Polymer\ Volume = (29.946329 * 10^{-10} cm)^3 = 2.6855 * 10^{-26} cm^3$

$$Density = \frac{2.32956274 * 10^{-26} grams}{2.6855 * 10^{-26} cm^3} = 0.867 \frac{g}{cm^3}$$

1500 Picosecond Simulation, 0atm, HDPE2000, 300K

$$Polymer\ Volume = (405278 * 10^{-10} cm)(37.5258 * 10^{-10} cm)(35.2742 * 10^{-10} cm)$$
$$= 5.3646 * 10^{-26} cm^3$$

$$Density = \frac{4.659125 * 10^{-26} grams}{5.3646 * 10^{-26} cm^3} = 0.868 \frac{g}{cm^3}$$

Appendix D

Globule Formation at Various Temperatures

The figures of this appendix are images at various time intervals of HDPE simulations. Four chains of 2000 pseudo atoms long were simulated at temperatures ranging from 300K to 800K at 0atm for 3000 picoseconds.

350 Kelvin Simulation

Figure 61, Figure 62, and Figure 63 below show the structure of the four chains simulated at 350K during the formation of a globule.

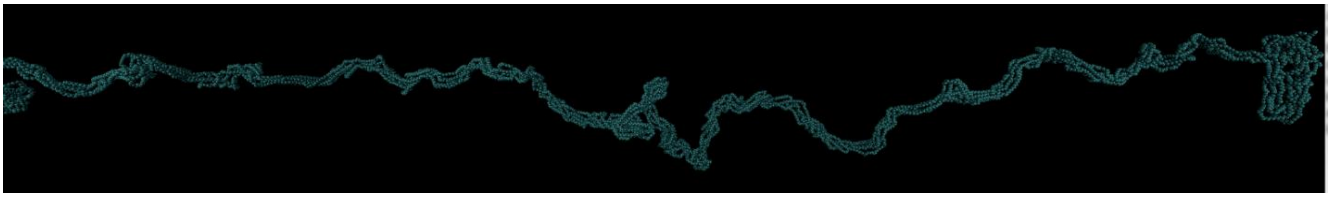

Figure 61: HDPE 350K (150 picoseconds)

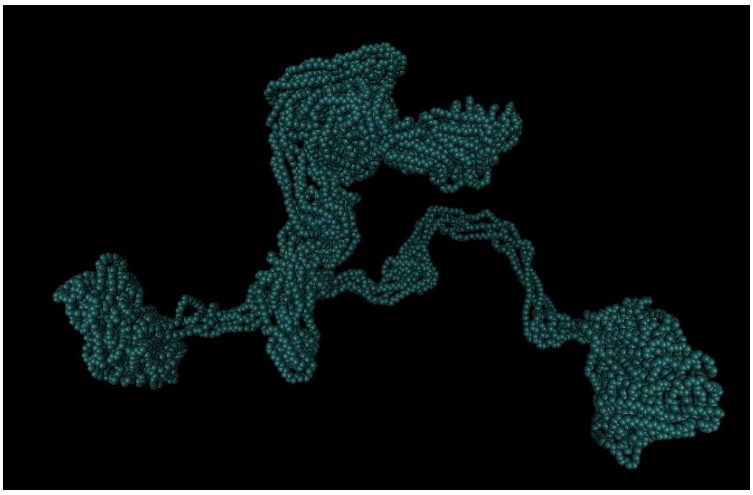

Figure 62: HDPE 350K (250 picoseconds)

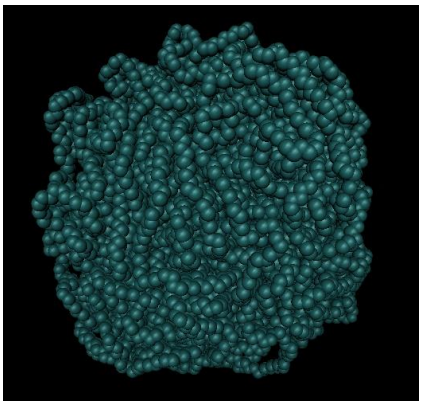

Figure 63: HDPE 350K (3000 picoseconds)

400 Kelvin Simulation

Figure 64, Figure 65, and Figure 66 below, show the structure of the four chains simulated at 400K.

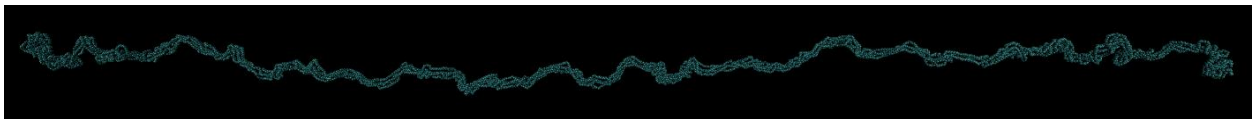

Figure 64: HDPE 400K (90 picoseconds)

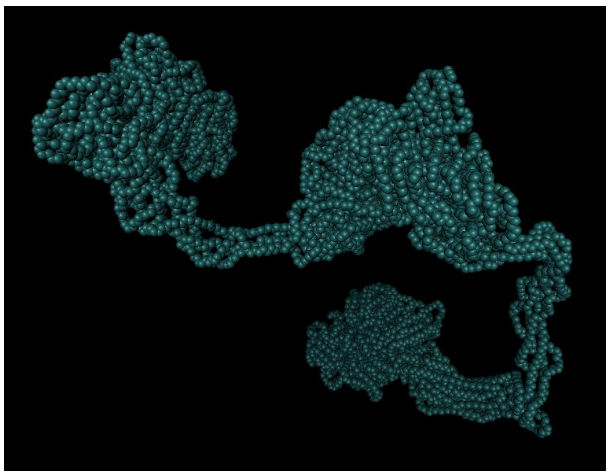

Figure 65: HDPE 400K (210 picoseconds)

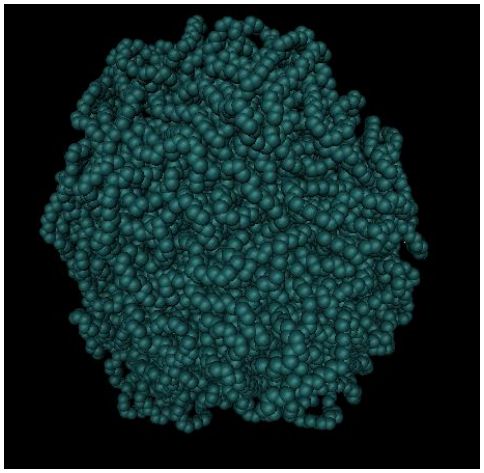

Figure 66: HDPE 400K (3000 picoseconds)

500 Kelvin Simulation

Figure 67, Figure 68, and Figure 69 below, show the structure of the four chains simulated at 500K.

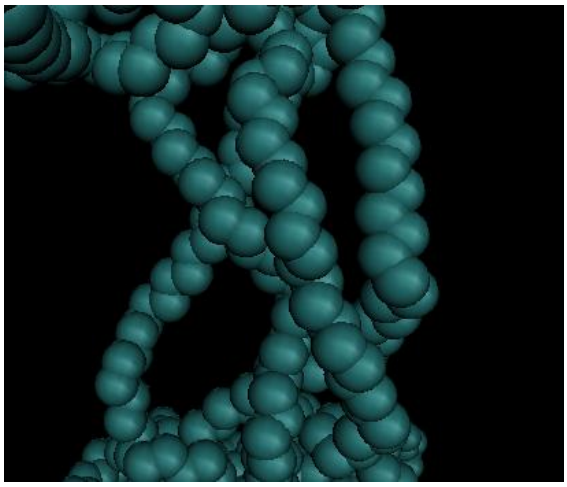

Figure 67: HDPE 500K (130 picoseconds)

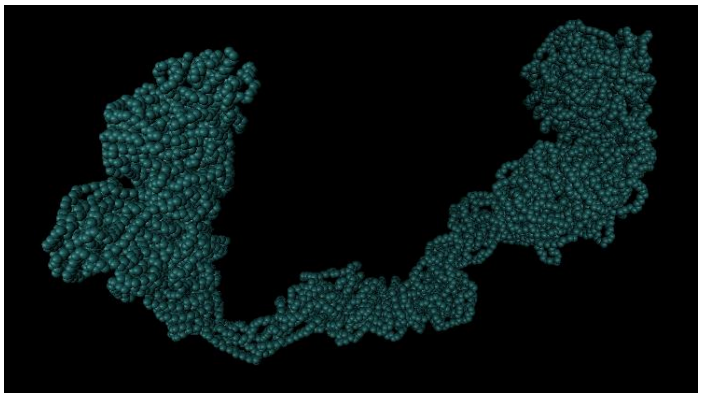

Figure 68: HDPE 500K (160 picoseconds)

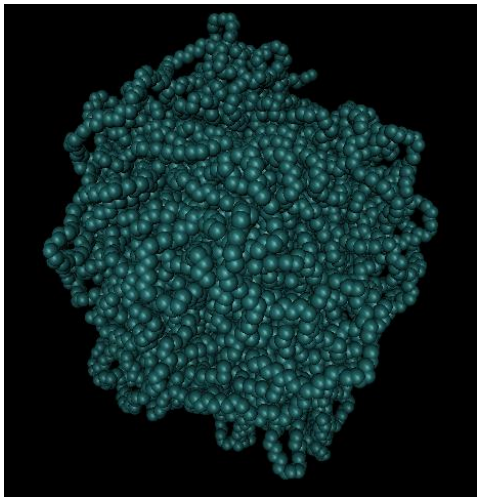

Figure 69: HDPE 500K (3000 picoseconds)

600 Kelvin Simulation

Figure 70 through Figure 74 below, show the structure of the four chains simulated at 600K. Figure 71 shows the initial point of globule formation. There is an abundance of kinetic energy in the system that prevents the globule from staying together at first pass. The momentum of the chains coming together only allows the globule to form for a brief moment before it starts to break apart. There is some oscillation between the globule state and the non-globule state as seen by the progression of Figure 70 to Figure 74.

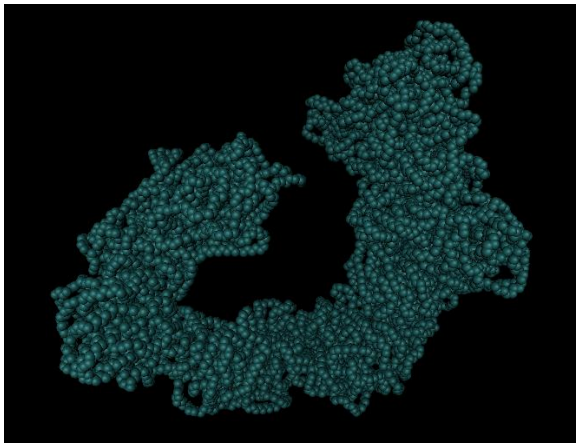

Figure 70: HDPE 600K (140 picoseconds)

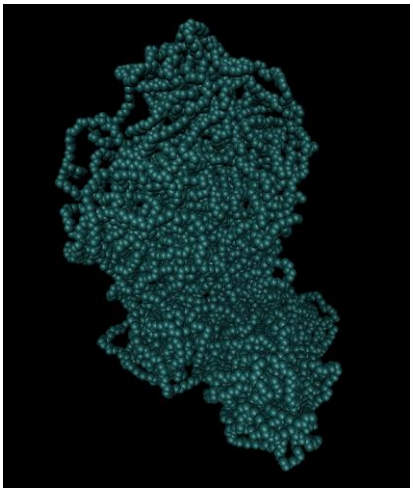

Figure 71: HDPE 600K (150 picoseconds)

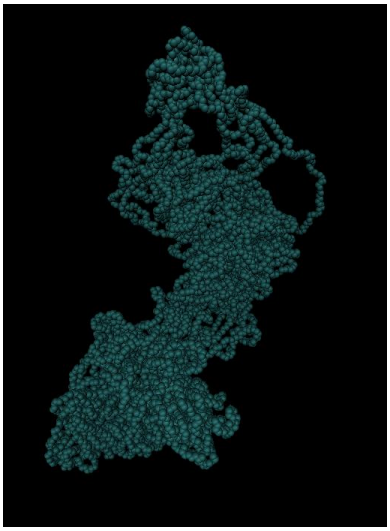

Figure 72: HDPE 600K (170 picoseconds)

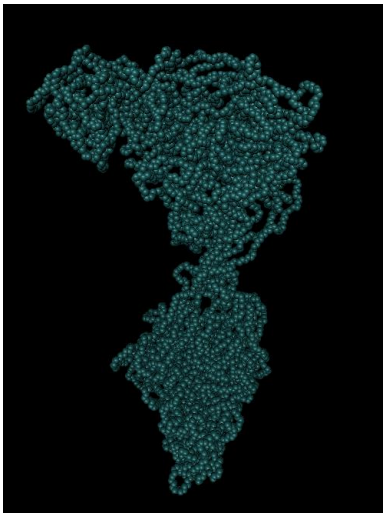

Figure 73: HDPE 600K (200 picoseconds)

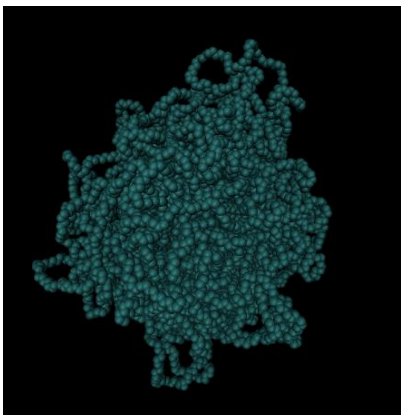

Figure 74: HDPE 600K (3000 picoseconds)

800 Kelvin Simulation

Figure 75 through Figure 78 below, show the structure of the four chains simulated at 800K. The oscillatory effect is seen as the momentum of the chains initially coming together overpowered the VDW attractive forces that hold together the globule. Figure 77 and Figure 78 depict melting as singular chains have broken away from the four adjacent chains from which they started, as well as from the globule as a whole.

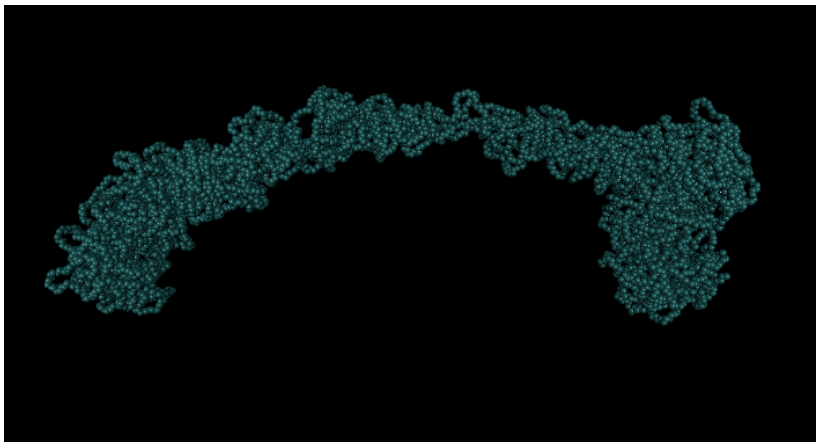

Figure 75: HDPE 800K (100 picoseconds)

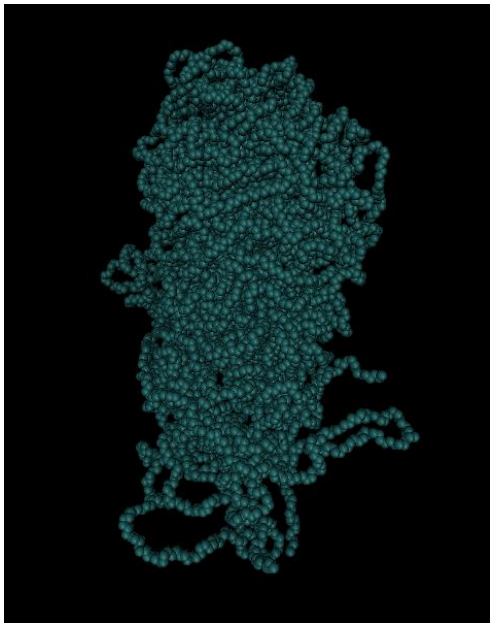

Figure 76: HDPE 800K (120 picoseconds)

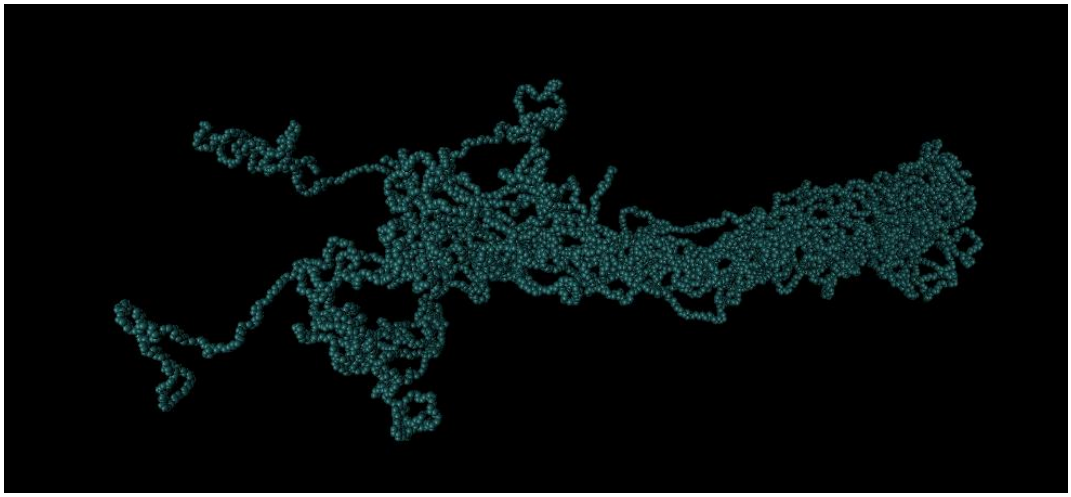

Figure 77: HDPE 800K (210 picoseconds)

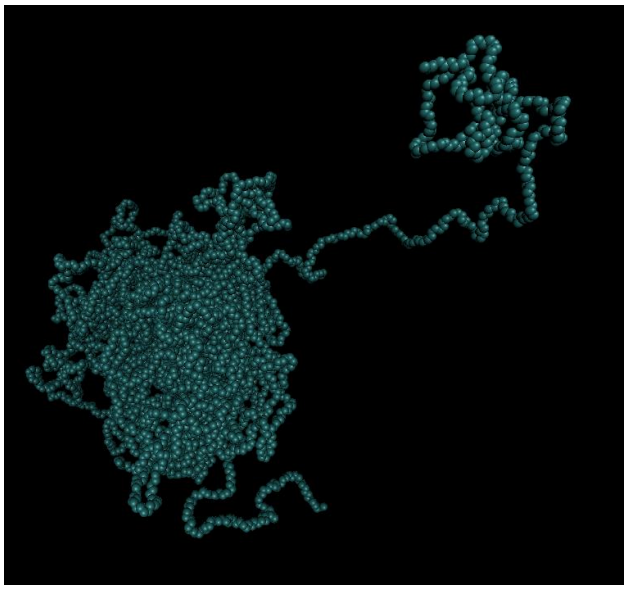

Figure 78: HDPE 800K (670 picoseconds)

Appendix E

DL_POLY2 Input Files

CONTROL, FIELD, and CONFIG input files are provided for the DL_POLY2 program below. HDPE files of one and four chain systems of 20 pseudo atoms long, PP files of a one chain system 50 pseudo atoms long, and LDPE files of a one chain system 200 pseudo atoms long were chosen.
